Abstract

This study leverages X-ray Phase-Contrast Tomography (XPCT) for detailed analysis of neurodegenerative diseases like Alzheimer's and Parkinson's, focusing on the 3D visualization and quantification of neuropathological features within fixed human postmortem tissue. XPCT, utilizing synchrotron radiation, offers micrometer and even sub-micron resolution, enabling the examination of intraneuronal aggregates—Lewy bodies, granulovacuolar degeneration, Hirano bodies, and neurofibrillary tangles—and extracellular amyloid plaques and cerebral amyloid angiopathy in the fixed human tissue. This approach surpasses aspects of traditional histology, integrating with neuropathology workflows for the identification and high-resolution

31 study of these features. It facilitates correlative studies and quanti-
32 tative electron density assessments, providing insights into the struc-
33 tural composition and distribution of neurodegenerative pathologies.

34 **Keywords:** neurodegeneration, x-ray phase-contrast tomography,
35 nano-imaging, holotomography, neuroimaging

36 1 Introduction

37 Neurodegenerative diseases are characterized by specific cellular and extra-
38 cellular protein aggregates. Studying their three-dimensional (3D) subcellular
39 localization and their structural composition is crucial to gain further insights
40 into ongoing pathological processes. Alzheimer’s disease (AD) and Parkinson’s
41 disease (PD) are the most prevalent neurodegenerative diseases and both are
42 characterized by intraneuronal aggregates consisting of tau aggregates in AD
43 or α -Synuclein aggregates in PD. To date, the comprehensive visualization and
44 quantitative assessment of these neuronal aggregates, alongside extracellular
45 amyloid plaques (in AD) or co-occurring cerebral amyloid angiopathy (CAA),
46 within a three-dimensional histological context has remained technologically
47 challenging. The coexistence of these pathologies in approximately 50% of
48 either AD or PD cases underscores the need for a unified method enabling
49 quantitative assessment of all these pathological features at subcellular reso-
50 lution with comparable quality to conventional histology [1, 2].

51 This gap between demand and capability of 3D histological imaging has
52 recently been closed by X-ray phase contrast tomography (XPCT). As a non-
53 destructive X-ray technique it offers high penetration, scalable resolution and
54 contrast for unstained native, liquid or paraffin embedded tissue [3–5]. Based
55 on high spatial coherence of synchrotron radiation (SR), and even laboratory
56 μ -focus sources, XPCT exploits phase contrast arising from free space wave
57 propagation, and applicability for studies of neurodegenerative diseases has
58 been demonstrated both for animal models as well as for human tissue, from
59 autopsy or biopsy. For AD models in mice, for example, XPCT allowed the
60 quantification of cellular quantify cellular aging [6] and the assessment of
61 plaque morphology [7, 8] in mouse cerebellum [9, 10]. Further, XPCT was
62 used to track neuronal loss and sequential evolution of multi-organ damage in
63 an experimental autoimmune encephalomyelitis (EAE) model [11–13]. Beyond
64 animal models, investigation of biopsies of human neuronal tissue by XPCT
65 [14] - also denoted as virtual histology - was used in [15] to resolve sub- μm
66 structures in the cerebellum, with notable changes in the cytoarchitecture
67 observed for multiple sclerosis (MS) [16]. In [17], correlative imaging of XPCT
68 and conventional histology was used to investigate AD related pathologies
69 of the hippocampal CA1-region, further investigated in [18], where an unex-
70 pected compactification of granular neurons was reported. On a larger scale,

71 imaging of an entire liquid-embedded human brain was recently demon-
72 strated, with the possibility to zoom in at certain areas of interest with voxel
73 sizes down to $1 \mu\text{m}$ [19].

74
75 In this work, we implement a multi-scale XPCT approach, by combining
76 parallel and cone beam illumination with highly coherent 3rd and 4th gener-
77 ation synchrotron beams to cover a wide range of scales, and to achieve high
78 quality reconstruction of human neuronal tissue, based on optimized optics,
79 phase retrieval and reconstruction, see Fig.1 for an overview over the experi-
80 mental approach (supplement for detailed experimental setup). We first scan
81 larger volumes of paraffin embedded tissue, fully compatible with conventional
82 neuropathology workflows, to identify regions of interest e.g. by immunohis-
83 tochemistry. We then study these structures of interest at high resolution
84 by zoom tomography in their native full three dimensionality, including here
85 intraneuronal aggregates like Lewy bodies (LB), granulovacuolar degeneration
86 (GVD), Hirano bodies (HB) and neurofibrillary tangles (NFTs) as well as
87 extracellular β -amyloid ($A\beta$) plaques and vascular amyloid depositions. Fur-
88 ther, with the 3D reconstructions obtained by non-destructive XPCT at hand,
89 we can then carry out as a proof-of-concept correlative investigations by con-
90 ventional immunohistochemistry. We are even able to compare for the first
91 time electron density of hallmark pathologies using the quantitative nature of
92 XPCT.

2 Results

93
94 Topographical investigation of pathologies of the central nervous system is a
95 difficult task due to the complex and folded three-dimensional architecture
96 of the brain. To develop a three dimensional μ -CT-scan method based on
97 X-ray Phase Contrast Tomography (XPCT) for neuropathological studies, a
98 multi-scale approach with microscopic resolution over macroscopic distances
99 is required. The measurements also need to be of comparable quality to
100 classical section based histology of formalin-fixed paraffin embedded (FFPE)
101 tissue blocks. In a label-free approach exploiting the contrast given by varying
102 electron densities in human tissue, we identify hallmark features even of subcel-
103 lular neurodegenerative pathologies like granulovacuolar degeneration (GVD),
104 Hirano bodies (HB) and Lewy bodies (LB). Additionally, accumulation of
105 amyloid aggregates as found either in extracellular plaques of Alzheimer's dis-
106 ease (AD) patients or cerebral amyloid angiopathy (CAA) are now accessible
107 to three dimensional exploration. Beyond qualitative analysis, this label-free
108 method allows for the quantitative comparison of electron densities across
109 different aggregates, thereby enhancing our understanding of the underlying
110 pathological processes.

Subsequently, small paraffin biopsies can be extracted from the tissue. **b** Illustration of selected intra- and extracellular dementia specific pathologies and biomarkers.

111 2.1 Subcellular 3D Compartment Analysis of Neurons

112 *Lewy Pathology*

113 Neuromelanin plays a pivotal role in neuroinflammatory processes during pro-
114 gression of Parkinson's disease (PD). Accumulation of neuromelanin granules
115 (NMG) within catecholaminergic neurons is a phenomenon that is most promi-
116 nent in humans and predominantly occurs in the substantia nigra, thus making
117 any animal model somewhat artificial with regard to this prototypical pathol-
118 ogy. To directly study the three dimensional subcellular distribution of LBs
119 and the NGMs in human tissue, a core punch (1 mm diameter) from a FFPE
120 block of the substantia nigra of a PD patient was retrieved and investigated
121 by XPCT. To achieve synchrotron measurements at different scales, a parallel
122 beam setup (SR1 at DESY, Hamburg) for a mesoscopic scale, and a cone beam
123 setup (SR2 at ESRF, Grenoble) to achieve higher magnification, were used.
124 In the 3D reconstruction (Figure 2a), it is observed that LBs are surrounded
125 by a considerable amount of NGMs and that LBs are spatially arranged dia-
126 metrically with respect to the nucleus. A layered substructure of the LB reveals
127 a dense homogenous core with a less intense surrounding shell.

128 *Hirano bodies*

129 Figure 2b highlights the ability of XPCT to capture the 3D structure of
130 the HBs in human hippocampal tissue, offering perspectives not achievable
131 through conventional histological methods. Remarkably, HBs exhibit a pro-
132 nounced contrast in XPCT compared to their typically faint appearance in
133 H&E stainings. The representation of Fig. 2b shows the 3D orientation of a
134 Hirano body (orange) with respect to the rest of the cell body (yellow) and the
135 cellular nucleus (blue). A histological (H&E stained) slice of the exact same
136 sample used for XPCT (Figure 2b) confirms the presence of this pathology
137 in HBs in this sample. This first human pathology based 3D representation
138 demonstrates the contact of the HB at the soma of the nerve cell but also
139 shows its disruptive morphology beyond usual nerve cell borders. As known
140 from previous studies Hirano bodies frequently co-occur with granulovacuolar
141 degeneration.

143 *Granulovacuolar Degeneration*

144 Figure 3a presents the findings on granulovacuolar degeneration (GVD) in
145 neurons from the CA1 hippocampal region of an AD patient. Until now, efforts
146 to image the GVD bodies were limited to two-dimensional stained histological
147 sections, other light microscopy techniques, or electron microscopy. Here, we
148 were able to record neurons with GVD in an unstained human tissue block
149 (Figure 3a), exploiting the nano-imaging capabilities at the SR2-setup. Besides
150 being able to visualize the varying densities inside the neuron (Figure 3a),
151 the high resolution, contrast and signal-to-noise ratio allow for a segmentation
152 of single subcellular granules and surrounding vacuoles (Figure 3 (a)). The

Fig. 2 Hallmark neuronal pathologies of human neurodegenerative pathologies measured by synchrotron μ CT scans (Part 1). **a** Virtual section through the reconstructed volume of a dopaminergic neuron (blue: neuron surface, yellow: Lewy body, red: neuromelanin granules, light green: nucleus, dark green: nucleolus), recorded with the cone beam SR2-setup and exemplary virtual serial slices of a LB. The top right image visualizes quantitatively determined electron densities. **b** 3D Reconstruction of a Hirano body from an AD patient with serial sections (SR2-setup) and a Hirano body in a HE staining from the exact measured tissue block.

153 annotations reveal a large network of vacuoles and granules. It also appears as
154 if the neuronal soma is enlarged by many granulovacuoles. Note that GVD was
155 also detectable in the large FOV reconstruction obtained from the SR1-setup,
156 see the supplemental document.

Fig. 3 Hallmark neuronal pathologies of human neurodegenerative pathologies measured by synchrotron μ CT scans (Part 2). **a** 3D rendering of manually segmented granulovacuoles from a CA1 neuron of an AD patient's hippocampus with virtual serial sections of GVD (SR2-setup) and correlative histological slice (H&E). **b** Tangle bearing neurons identified by correlative immunohistochemistry (at8-antibody) and corresponding XPCT scan (SR1-setup).

157 *Neurofibrillary Tangles*

158 Neurofibrillary tangles (NFTs) consist of hyperphosphorylated tau aggregates
159 and AD cases included in this study were selected to have a high Braak stage
160 (5-6). Interestingly, e.g. compared to Hirano or Lewy bodies, the intracellular
161 tau-aggregates were difficult to identify in XPCT. To ensure identification of
162 single neurons with NFTs, we optimized the correlative immunohistochemical
163 (IHC) analysis of the core punches after imaging the sample by the synchrotron.
164 A detailed description of the correlation workflow can be found in
165 the supplementary document. The staining quality was not reduced, and identifi-
166 cation of single tangles by at8 antibody was possible. In a manual image
167 registration approach using landmarks like blood vessels, we were able to iden-
168 tify the exact neuron both in the XPCT as well as in the IHC stained slice. This
169 allowed us to investigate electron density in affected and non-affected neurons
170 and revealed only slight compositional heterogeneities of electron densities in
171 the soma of affected neurons (Figure 3b). In summary, the pathology of intra-
172 neuronal tangles appears less densely packed, particularly when compared to

173 Hirano bodies. Moreover, in contrast to Lewy bodies, the contrast of intraneu-
174 ronal tangles is not as uniform, making them morphologically challenging to
175 distinguish from normal neuronal structures.
176 Additional data on all findings can be found in the supplementary document.

177 **2.2 Identification of extracellular and vascular amyloid** 178 **aggregates**

179 Aside from intraneuronal aggregates and their influence on cognitive function,
180 amyloid- β species, which are cleaved extracellular peptides, have been central
181 to neurodegenerative research for decades and are currently a molecular tar-
182 get for potential therapies. However, current clinical CT scans still lack the
183 capability to visualize different amyloid plaques types or detect changes in
184 small arterioles, veins, or even capillaries e.g. in cerebral amyloid angiopathy
185 (CAA). In response to the limitations of traditional imaging techniques, our
186 approach first involves a detailed characterization of amyloid- β plaques using
187 the cone-beam high-resolution setup. Secondly, the capabilities to investigate
188 CAA with the parallel beam setup are demonstrated.

189 *Amyloid Plaques*

190 Extracellular amyloid plaques, characterized by varying amyloid/protein den-
191 sities, exhibit distinct morphological features. Especially the core of an amyloid
192 plaque is clearly delineable, even in the parallel beamline of the SR1-setup,
193 which, with its effective pixel size of 650 nm, enables the study of its 3D dis-
194 tribution in larger tissue volumes. In this project, the improved resolution
195 offered by the SR2-setup with a cone beam even allows to identify the shell of
196 a cored plaque with good contrast compared to the underlying glial matrix,
197 as visualized in figure 4a. Employing the correlation workflow previously out-
198 lined, IHC images of stained amyloid plaques (using the 6E10 antibody) were
199 juxtaposed with the corresponding XPCT measurements. Due to their size,
200 the same amyloid plaque can easily be identified in both measurements. The
201 second row of figure 4a displays cored plaques measured in the SR1 beam-
202 line, clearly identified by correlative immunohistochemistry, and their three
203 dimensional distribution. In the next step the question arose if with the abil-
204 ity to detect amyloid plaques also amyloid species in blood vessels would be
205 accessible to μ -CT.

206 *Cerebral Amyloid Angiopathy*

207 The amyloid deposits in cerebral amyloid angiopathy (CAA) are also well
208 detectable by XPCT, even by the SR1-setup, thus enabling a multi-scale
209 approach. In correlative immunohistochemistry it becomes clear that affected
210 vessel walls show slightly increased contrast, see figure 4b. The 3D reconstruc-
211 tion of one exemplary affected small meningeal arteriole demonstrates the
212 varying vessel diameter. This highly precise μ -CT demonstrates a new scale
213 for identification of even minor blood vessel changes invisible to angiography

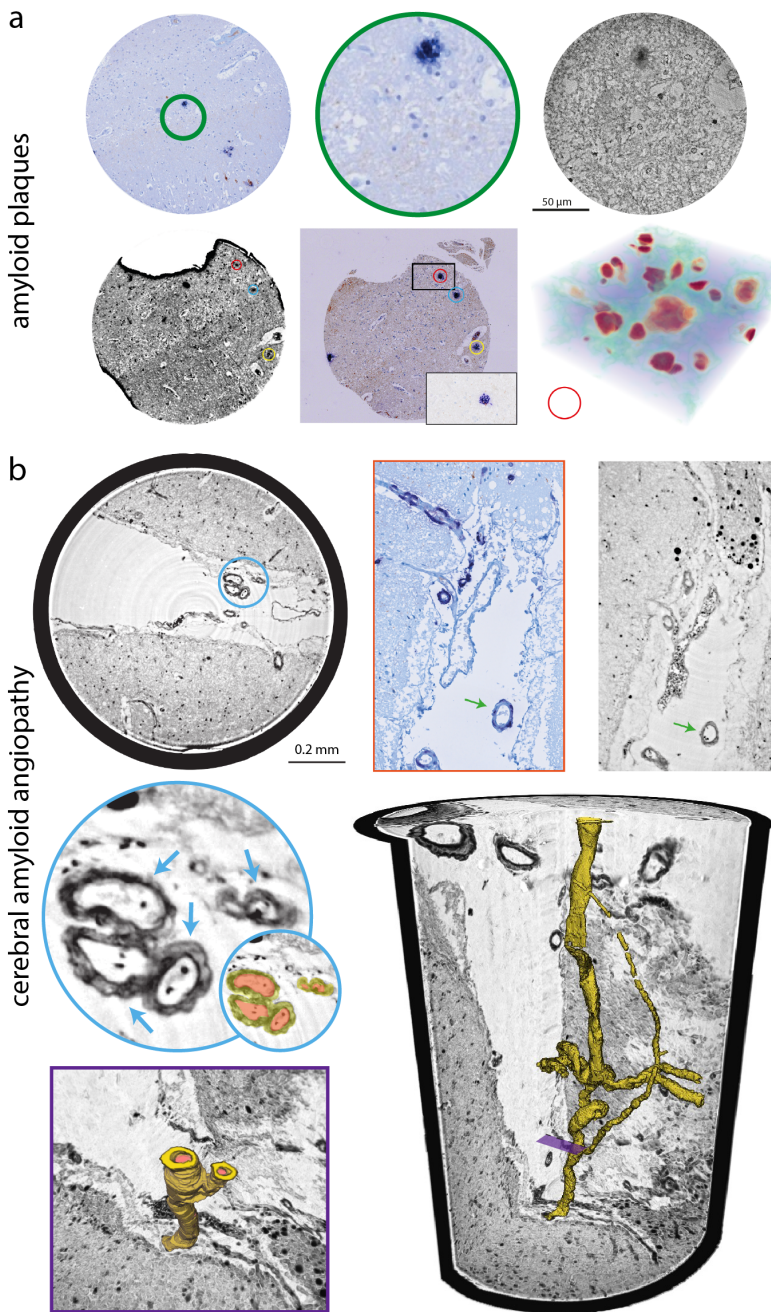

Fig. 4 Amyloid plaques and Cerebral Amyloid Angiopathy visualized by XPCT. a Correlative IHC of beta amyloid positive plaques (6E10, FastBlue) and high resolution XPCT (SR2-setup). Second row low resolution XPCT with correlative IHC (6E10) and three dimensional representation of staining nuclei, blood vessels and plaques. b Cerebral Amyloid Angiopathy with correlative histology and 3D rendering of an affected meningeal blood vessel (green arrow).

214 and investigations of branching arteries and arterioles, veins and even of brain
215 capillaries.

216

217 Additional data on all findings can be found in the supplementary document.

218 **2.3 Quantitative Comparison of Electron Densities**

219 Building on the use of X-ray Phase Contrast Tomography (XPCT) to delve
220 into neurodegenerative pathologies, the electron density of protein aggregates
221 was studied here featuring various pathological features. Unlike conventional
222 histology, which relies on staining-specific amplification methods, the image
223 formation of XPCT is quantitatively linked to the electron density distribu-
224 tion. Using standardized acquisition and analysis, the electron density can be
225 calculated from the phase shifts obtained by phase retrieval. Since electron or
226 effectively mass density effectively mirrors biological parameters such as fib-
227 ril density or metal involvement, it can provide important information on a
228 given pathology. Importantly, the standardization allows a direct comparison
229 of neuronal and extracellular neurodegenerative findings, even across different
230 diseases (for details on electron density calculation, see supplement).

231 This quantitative approach revealed small inhomogeneities on the scale of 2-3
232 μm within the Lewy body, suggesting the presence of encased organelles (see
233 **5a**). Notably, the calculated quantitative electron density revealed a circular
234 arrangement of hypodense, potentially lysosomal structures at the outer part
235 of the LB, providing insights into the subcellular composition of this aggregate.
236 The inherent quantitative capability of XPCT facilitates the assignment of
237 Hirano bodies to similar electron densities comparable to those observed in
238 neuromelanin granules (see **5a + b**). This comparison underscores the utility
239 of XPCT in differentiating between various intracellular aggregates based on
240 their electron density profiles.

241 Granulovacuolar degeneration in contrast does not display a homogeneous
242 distribution of electron densities, but it is also not clearly bimodal. This is
243 suggestive of vacuoles with granules which show a slowly increasing density
244 towards their core.

245 Lastly the extracellular amyloid plaque seems rather loose and only the core
246 shows a slight increase in electron density.

247 This analysis not only highlights the heterogeneity within neurodegenerative
248 pathologies but also emphasizes the potential of quantitative imaging tech-
249 niques in enhancing our understanding of these diseases at a microstructural
250 level.

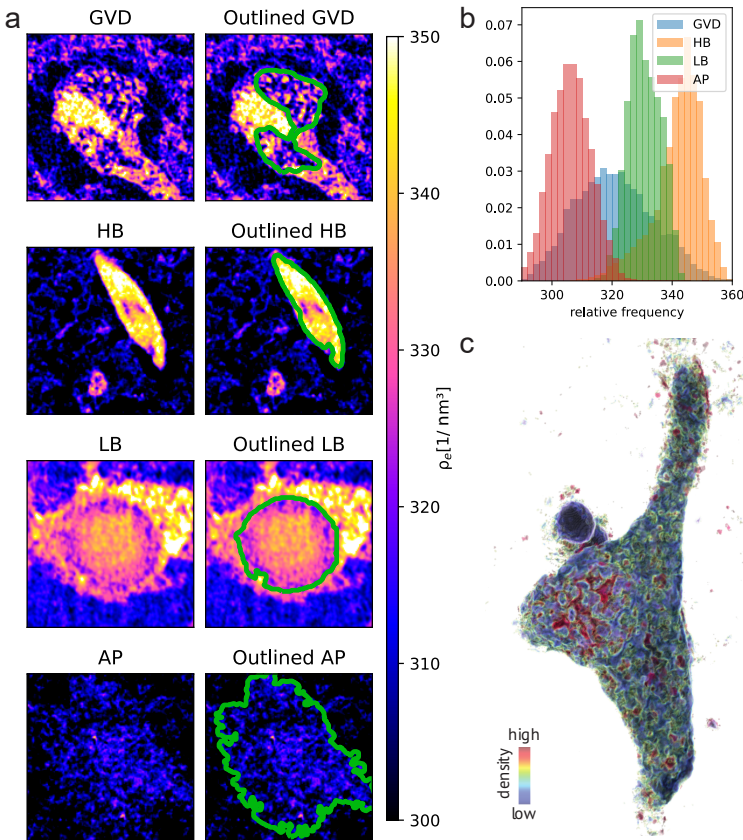

Fig. 5 Hallmark electron densities of human neurodegenerative pathologies measured by synchrotron XPCT scans. **a** showcases cross-sectional calculated electron densities of neurodegenerative pathologies, with each row representing a different pathology (width of image $20 \mu\text{m}$). The right images feature the same section overlaid with a green ROI delineating the electron density measurement for **b**. Panel **b** presents the electron density histograms for granulovacuolar degeneration (GVD), Hirano bodies (HB), Lewy bodies (LB), and amyloid plaques (AP), illustrating the distribution of electron densities within each pathological feature. Panel **c** depicts a high-resolution calculated electron density image of a neuron with granulovacuolar degeneration, color-coded to represent electron density levels from high (red) to low (blue), highlighting the intricate density variations within GVD.

251

3 Discussion

252

253

254

255

256

257

258

259

Protein aggregates are a central hallmark of several neurodegenerative diseases instructing genetic and pathogenetic research; however, their formation, cytoplasmic embedding, and role for neuronal toxicity are not resolved. In this work, we leveraged advanced quantitative imaging, X-ray phase contrast tomography (XPCT), combined with correlative conventional immunohistochemistry to identify and compare in their full three dimensionality (3D) and at sub-cellular scale disease defining pathological protein aggregates. Noteworthy, this is compatible with the standard workflows of clinical pathology

260 for *post mortem* cohorts of patients suffering from neurodegenerative diseases.
261 This approach enabled us to conduct a quantitative comparison of electron
262 densities across different aggregates. By combining XPCT with correlative
263 conventional immunohistochemistry, we are now even able to stain with any
264 antibody, thereby facilitating accurate identification and measurement of low
265 electron contrast structures like tangles or vascular amyloid deposits.

266 While the general compatibility of XPCT and FFPE samples has been pre-
267 viously established [17, 18, 20], we have demonstrated that improvements
268 in resolution and contrast, facilitated by the specificities of SR2 setup (see
269 below), are sufficient to identify and to quantify also subcellular neuronal
270 pathologies, such as Lewy bodies (LB), granulovacuolar degeneration (GVD)
271 or Hirano bodies (HB). To our knowledge, some of these have never or rarely
272 been imaged in 3D before. While the 3D inspection alone allowed us to better
273 understand the nature of the aggregates, the quantitative analysis of XPCT
274 contrast values revealed significant differences in electron densities between
275 subcellular aggregates. Note that this requires monochromatic illumination,
276 and reference values given by the embedding matrix (paraffin), as well as
277 advanced phase retrieval algorithms [21, 22].

278
279 By far the highest electron density was found in Hirano bodies. This finding is
280 in line with previous electron microscopy studies using quick-freeze deep-etch
281 technology on the ultrastructure of HBs. It was demonstrated that HBs are
282 intracellular and densely packed fibrillar aggregates [23].

283 Additionally, the size and orientation of protein aggregates relative to the cel-
284 lular body and nucleus may have significant implications, offering valuable
285 insights into their development within the cell. For instance, the peculiar ori-
286 entation of HB revealed through 3D virtual histology by XPCT (see 2b) may
287 give indications for its mechanism of formation. Likewise, the 3D association of
288 NM around Lewy bodies observed here (see 2a), is noteworthy, increasing the
289 evidence for association of alpha-synuclein with neuromelanin pigments from
290 extensive two dimensional histological studies [24]. The usual size of LB ranges
291 from 5 to 25 μm in diameter with a dense eosinophilic core of filamentous and
292 granular material surrounded by radially oriented filaments [25, 26]. This core
293 and the filamentous shell are likely to be reflected in the XPCT reconstruction
294 in form of elevated levels of electron density by XPCT. There is also recent
295 evidence using confocal as well as super-resolution stimulated emission deple-
296 tion (STED)-microscopy combined with electron microscopy and tomography
297 that dense lysosomal structures and a shell of distorted mitochondria surround
298 some of the LB inclusions (see Fig. 7 of [27]). In this study we are able to iden-
299 tify even of these LB substructures LBs in terms of electron density, owing to
300 the increased resolution of the SR2 setup.

301 For the first time, correlative immunohistochemistry (IHC) facilitated, at a sin-
302 gle cell resolution, the identification of neurons with NFTs in XPCT. Even
303 though the identification of tangle-bearing neurons in the investigated samples
304 was not yet possible by XPCT alone, the highly precise measurements and

305 definitive identification of tangles through conventional methods allow us to
306 draw conclusions. Obviously, compared to HBs and LBs, tangles are not homo-
307 geneously increasing the electron density of affected neuronal cytoplasm to a
308 significant level. Comparing this finding to existing electron microscopy studies
309 demonstrates that NFTs are rather well surrounded by subcellular organelles
310 and do not fill up densely the neuron [28, 29]. This underscores that XPCT
311 serves a complementary method to highly advanced cryo-EM resolving atomic
312 structure of protein-aggregates, for example, in tau-filaments in Alzheimer’s
313 disease [30]. We can now conclude, that the pathology of tangles is mediated
314 more by stiffening the cytoskeleton and especially the microtubules, obviously
315 leading to various cellular dysfunctions, rather than by completely replacing
316 existing subcellular organelles as observed in HBs. It also raises the question
317 if extended XPCT methods either implementing staining by X-ray contrast
318 agents or by achievement of even higher resolution will be able to identify
319 affected pathological tau-filaments. Note that the resolution of XPCT has not
320 reached its fundamental limits, and can be expected to be further increased
321 by ongoing instrumental improvements.

322 Correlative IHC further improved our detection sensitivity of $A\beta$ plaques as
323 demonstrated by high resolution images of the SR2-setup (see Fig. 4a). $A\beta$
324 plaques were recently identified by XPCT in unstained human autopsy brain
325 tissue by Chourrout et al. [7], reporting varying contrast in mice and human
326 supposedly depending on the degree of calcium accumulation, in line with
327 findings by Toepperwien et al. where mineralized plaques could be clearly
328 observed even with in-house μ CT instrumentation [15].

329 Here we are now able to measure the electron density quantitatively. The core
330 of $A\beta$ plaques shows a significantly higher electron density while the less dense
331 shell becomes only barely visible in the high resolution SR2-setup. One may
332 wonder why some structures like amyloid plaques or tangles in XPCT are
333 especially difficult to detect. Since for FFPE tissue contrast is generated by
334 the difference with respect to the embedding paraffin matrix, this can happen
335 for organelles or structures which happen to exhibit similar density as the
336 matrix. As a solution, contrast variation by different embedding media can be
337 employed [3].

338 While the voxel size and instrumental resolution (as determined for high
339 contrast objects) are clearly sufficient to image the targeted pathologies at
340 sub-cellular scale, the reconstruction of the FFPE tissue still exhibits sub-
341 stantial noise. In fact, as explained in the paragraph above, it is the low
342 contrast of specific features such as unmineralized plaques which limits the
343 3D structural information gained rather than the instrumental resolution.
344 For the SR2-setup, in particular, 50 nm (half period) resolution has been
345 achieved in inorganic samples with high contrast or in metalized biological
346 specimens [5, 31]. In order to reduce noise and to increase contrast in the
347 present unlabeled FFPE tissues, one can either increase dose or decrease the
348 photon energy E . Since the phase shift $\Delta\phi$ per resolution element scales with
349 E^{-1} (away from absorption edges), the contrast increases accordingly. Note

350 that the diameter of the biopsy punches would clearly allow a reduction of
351 E by at least a factor of two. Future extension of this work may also include
352 recently developed X-ray stains [32–35] to improve contrast not only for dis-
353 tinct structural hallmarks of neurodegeneration covered in this work, but also
354 for the individual cellular components e.g. axons, dendrites or synapses, or
355 the myelin sheath which would open up a new perspective for X-ray imaging
356 of myelin-associated diseases, such as multiple sclerosis.

357
358 While large volumes can be screened systematically in contrast to imaging of
359 subsequent sections, the relevant targets still have to be identified, and 3D
360 imaging ideally includes a subsequent targeted zoom capability. Here we have
361 met this challenge by a multi-scale approach, where large field of view scans
362 with a parallel undulator beam are combined with zoom tomography based
363 on cone beam magnification, using a nanofocus optic serving as a secondary
364 source for holographic imaging. Importantly, the combination of high brilliance
365 and high resolution scintillators allows for the identification of the features of
366 interest already in the parallel beam setting (SR1-setup), where 1.5 mm FOV
367 was scanned with 650 nm voxel size in little more than a minute per scan. Note
368 that the FOV and volume throughput can be further increased by stitching
369 several of such scans. We then use high resolution cone beam recordings (SR2-
370 setup) to image the sub-cellular structures of interest at higher resolution.
371 The high instrumental stability and unprecedented high flux of this in-vacuum
372 instrument and sub-50 nm KB nano-focus in combination with elevated photon
373 flux of $2 \cdot 10^{11}$ ph/s results in unprecedented image quality for 3D imaging of
374 pathological hallmarks.

375 Unstained tissue preserved in formalin-fixed paraffin embedded (FFPE) tissue
376 blocks can be used without further constraints or preparation steps, apart
377 from punch biopsies with mm-sized diameter to obtain cylindrical specimens
378 for XPCT. After the non-destructive scans, these can be embedded again, sec-
379 tioned and inspected by conventional histology, enabling correlative imaging.

380
381 Finally, beyond *post mortem* autopsies, XPCT based histopathology can also
382 be performed on human brain tissue collected during surgery. To this end, au-
383 tomated workflows, remote access and mail-in sample processing are currently
384 implemented or considered by several synchrotron facilities.

385 4 Methods

386 *Sample preparation*

387 Human brain tissue from individuals who underwent diagnostic autopsy in
388 the context of routine clinical care was obtained from the archives of the
389 Department of Neuropathology UMG in accordance with the UMG ethics
390 committee. Small brain tissue blocks were dissected from 10% formalin-fixed
391 brain slices, dehydrated, and paraffin embedded (see [18]). One FFPE tissue

392 block measures about $2 \times 3 \times 0.3 \text{ cm}^3$. In total, 11 samples from four individ-
393 uals were selected for the study, including 8 samples from the hippocampal
394 CA1 region (four with immunohistochemically confirmed neurofibrillary
395 tangles (see immunohistochemistry)), one white matter control sample, one
396 sample from the substantia nigra from a PD patient and one from the cortex
397 including the leptomeninges of a patient with CAA. Regions of interest were
398 defined on an adjacent histological section. To prepare the samples for XPCT
399 image acquisition, cylindrical 1 mm biopsies were extracted from the paraffin
400 blocks, inserted in a polyimide tube and placed on Huber pins. After imaging
401 these paraffin blocks were again embedded in paraffin and processed further
402 for histological or immunohistochemical analysis.

403

404 ***Immunohistochemistry***

405 Immunohistochemistry was performed on 1-2 μm thick slices cut from the
406 paraffin block with a microtome. Pretreatment included hydrogen peroxide
407 as well as formic acid (98%) (for $A\beta$ immunohistochemistry only), blocking in
408 10% normal goat serum as well as heat antigen retrieval (citrate buffer, pH 6).
409 Primary antibody (tau: mouse, clone at8, Thermo Fisher Scientific, 1:100; β -
410 Amyloid: mouse, clone 6E10, Zytomed Systems GmbH, 1:500) incubation over
411 night was followed by secondary antibody incubation either coupled to alkaline
412 phosphatase (polyclonal goat anti-mouse, Dako, 1:50) or to biotin (monoclonal
413 sheep anti-mouse, GE Healthcare Life Sciences, 1:100). Slides were developed
414 using avidin-peroxidase with DAB and/or using the fast blue solution.

415 ***Propagation-based phase-contrast imaging at the synchrotron***

416 Synchrotron radiation allows for imaging with high coherence and brilliance
417 and can cover multiple length scales down to sub-100 nm resolution. In this
418 work we take advantage of a multiscale XPCT approach, using the paral-
419 lel beam (SR1) configuration of the GINIX endstation installed at the P10
420 beamline of the PETRA III storage ring (DESY, Hamburg) [36] and the nano-
421 imaging beamline (SR2) ID16A (ESRF, Grenoble, France). While the former
422 is optimized for larger FOV with a parallel beam geometry, the latter is dedi-
423 cated to propagation-based holographic tomography of biological samples, and
424 operates in the hard X-ray regime (17-33.6 keV). To achieve high resolutions,
425 the beam is focused by a pair of Kirkpatrick-Baez (KB) mirrors. Both provide
426 quantitative phase contrast which allows to retrieve information on the electron
427 density in the sample, making them especially useful for biomedical applica-
428 tions. The two configurations can be used complementary to study biological
429 tissue at multiple scales. Details on the setup and acquisition parameters can
430 be found in the Supplementary Document.

- 431 • SR1: The imaging procedure involved an overview scan using a field of view
432 (FOV) of approximately 1.5 mm. Therefore, a parallel-beam configuration
433 was employed, enabling continuous rotation and resulting in an overall scan

time of approximately 2 minutes. The acquisition of single-distance tomograms involved 3000 projections captured over a 360° rotation. To achieve a well-defined photon energy for studying the tissue, a Si(111) channel-cut monochromator was utilized, eliminating the broad band-pass limitations inherent in in-house CT systems. On the registration side, a high-resolution detection system (Optique Peter, France) with a 50 mm-thick LuAG:Ce scintillator and a 10× magnifying microscope objective [36] was coupled with the sCMOS camera pco.edge 5.5 (PCO, Germany). The camera performs with a maximum frame rate of 100 Hz, utilizing a rolling shutter and fast scan mode. This configuration yielded an effective pixel size of 0.65 μm, with an approximate total exposure time of 96 s. To achieve the desired imaging conditions, certain components such as KB-mirrors, waveguide and the fast shutter were removed from the beam path. Additionally, the beam size was adjusted to approximately 2×2 mm using an upstream slit system (refer to Figure 1d).

- SR2: The nano-imaging beamline ID16A provides a highly-brilliant, low-divergent beam optimal for three dimensional high-resolution imaging of biological samples or other nanomaterials e.g. in batteries. With its multi-layer monochromator and focusing KB-mirrors, it allows for photon energies of either 17.1 or 33.6 keV and a photon flux of up to $4.1 \cdot 10^{11} \frac{ph}{s}$. The cone beam geometry enables a magnification of the projected pixels resulting in possible effective pixel sizes px_{eff} of less than 10 nm. The monochromaticity allows for a subsequent quantitative analysis and retrieval of sample characteristics such as electron density. Due to the strong magnification and high coherence, phase propagation can be very accurately recorded and reconstructed from the strongly holographic projections ($F \ll 1$). For detection, a XIMEA sCMOS based indirect imaging detector with 6144 x 6144 pixel (10 μm physical pixel size) and a 10× magnifying microscope objective was used. In this experiment the projections were binned (3×3), with effective pixel sizes ranging from 90 to 140 nm. 2000 projections were recorded per scan with additional random sample displacement for every angle to correct for wavefront inhomogeneities and therefore avoiding ring artifacts [37]. Tomographic scans were acquired at four distances to account for zero crossings in the CTF phase reconstruction [38]. From the four distances, the one with the highest resolution and largest FOV is combined, resulting in an "extended FOV" of 3216² pixel in the resulting tomographic slices (refer to Figure 1e).

Data processing

Projections are acquired and saved using the .tiff or .raw format. After flat field and dark image correction, operating in the holographic regime, phase retrieval was performed using either the contrast transfer function (CTF, [38, 39]), the nonlinear Tikhonov (NLT, [40]) or a Paganin-based iterative

477 scheme [41] (see supplemental document). On the phase retrieved projec-
478 tions, ring removal techniques were conducted (only random displacement at
479 SR2-setup) as well as an automatic rotation axis correction. Tomographic
480 reconstruction was then performed by either filtered back projection (par-
481 allel beam, SR1) or the Feldkamp-Davis-Kress (FDK, [42]) algorithm. Both
482 techniques are implemented in the ASTRA-Toolbox [43] for MATLAB and
483 incorporated into the HolotomoToolbox [22]. Further details on the different
484 reconstruction schemes can be found in the supplemental document.

486 *Segmentation and visualization of cell components*

487 After tomographic reconstruction of the recorded, phase-retrieved, projections
488 and visual inspection by practising pathologists, different structures were pro-
489 posed for further analysis. After selection, segmentation was conducted using
490 seeded watershed algorithms, deep learning based techniques (webKnossos
491 [44], scalable minds GmbH, Potsdam, Germany) or simple thresholding. Sub-
492 sequently, rendering software such as NVIDIA IndeX (NVIDIA, Santa Clara,
493 US), Avizo (Thermo Fisher Scientific, Waltham, US) and ZEISS arivis (Carl
494 Zeiss AG, Oberkochen, Germany) was used for a three-dimensional visualiza-
495 tion of the dataset. For additional post processing such as orthogonal views
496 and maximum intensity projections the Fiji software was used [45]. Details on
497 segmentation can be found in the supplemental document.

498 **Data availability**

499 Raw data were generated at ESRF and DESY. Raw data will be released and
500 made public two years after the beamtime. All treated datasets are available
501 from the corresponding author on request. Exemplary datasets that sup-
502 port the findings of this study will be openly available in GRO.data upon
503 publication.

504 **Contribution statement**

505 JR and JF contributed equally to this work. TS, CS, JF and JR conceived the
506 experiments and analysis. JF selected and prepared the samples. JR, TS con-
507 ducted the synchrotron experiments, together with ME, acting as local contact
508 at the ID16A beamline. JR performed data processing, image reconstruction
509 and visualization. JF annotated data and performed data processing. JR, JF,
510 and CS interpreted the results in terms of neuropathology. TS, CS, JF and JR
511 wrote the manuscript. All authors reviewed the manuscript.

512 **Acknowledgement**

513 We thank Markus Osterhoff, Michael Sprung and Fabian Westermeier for their
514 continuous support at the instrument GINIX/P10 (PETRA III, DESY). The
515 work was funded by the Deutsche Forschungsgemeinschaft (DFG, German

516 Research Foundation) – Project-ID 432680300 – SFB 1456/A03 Mathematics
517 of Experiment and EXC 2067/1-390729940. We also acknowledge assistance in
518 visualization with NVIDIA IndeX (NVIDIA Corporation, USA).
