Word count: Abstract 270, Introduction to Discussion 3104
Abstract

Background: Mindfulness interventions have not been rigorously evaluated in episodic migraine.

Objective: To evaluate the efficacy of an enhanced mindfulness based stress reduction (MBSR+) versus stress management for headache (SMH).

Design, Setting, Participants: Randomized, assessor-blind, clinical trial of 98 adults with episodic migraine recruited at a single academic center comparing MBSR+ (n=50) to SMH (n=48). (https://clinicaltrials.gov/ct2/show/NCT02133209)

Intervention: MBSR+ and SMH were delivered weekly by group for 8 weeks, then bi-weekly for another 8 weeks.

Measurements: The primary outcome was reduction in headache days from baseline to 20 weeks. MRI outcomes included activity of left dorsolateral prefrontal cortex (DLPFC) and cognitive task network during cognitive challenge, resting state connectivity of right dorsal anterior insula (dαINS) to DLPFC and cognitive task network, and gray matter volume of DLPFC, dαINS, and anterior midcingulate. Secondary outcomes were headache-related disability, pain severity, response to treatment, migraine days, and MRI whole-brain analyses.

Results: Reduction in headache days from baseline to 20 weeks was greater for MBSR+ (7.8 [95%CI, 6.9-8.8] to 4.6 [95%CI, 3.7-5.6]) than for SMH (7.7 [95%CI 6.7-8.7] to 6.0 [95%CI, 4.9-7.0]) (P=0.04). 52% of the MBSR+ group showed a response to treatment (50% reduction in headache days) compared with 23% in the SMH group (P=0.004). Reduction in headache-related disability was greater for MBSR+ (59.6 [95%CI, 57.9-61.3] to 54.6 [95%CI, 52.9-56.4]) than SMH (59.6 [95%CI, 57.7-61.5] to 57.5 [95%CI, 55.5-59.4]) (P=0.02). There were no differences in clinical outcomes at 52 weeks or MRI outcomes at 20 weeks, although changes related to cognitive networks with MBSR+ were observed.

Limitations: A single site and likely self-selection bias.

Conclusions: MBSR+ is an effective treatment option for episodic migraine.
Introduction

Migraine is a severe and often disabling neurological disorder (1, 2) and standard preventative agents frequently create challenging side-effects. (3, 4) Migraine guidelines (5) include nonpharmacological preventative treatments, and mindfulness-based stress reduction (MBSR) recently has been shown to improve pain and functional outcomes in chronic low back pain. (6) Yet meditation and mindfulness therapies show only modest benefits to date in reducing the frequency of migraine. (7, 8) The outcomes of MBSR in reducing pain (9) and migraine frequency (7) may improve if training is enhanced to include a longer period of learning, as greater home practice yields better outcomes in MBSR. (10) Since medication can contribute to the frequency of headache, (11) MBSR may be an effective nonpharmacological prevention strategy that has become widely available throughout the United States and Europe in recent years.

Migraine headaches are due to acute alterations in the trigeminalvascular system and changes in brain perfusion include widespread increases and decreases in brain activity. (12-14) Beyond the changes known to occur during attacks, mild cognitive deficits occur between attacks (15, 16) and brain structure is altered relative to controls. (17, 18) These brain changes involve cognitive and emotional circuits, (19) particularly the insula, (20) left dorsolateral prefrontal cortex (DLPFC), and anterior/mid cingulate cortex (ACC/MCC). (21) The demands of recurring pain deplete cognitive and emotional resources, (22) and treatments that increase the efficiency of information processing, or cognitive efficiency, may be particularly beneficial for painful conditions such as migraine. The practice of mindfulness meditation appears to increase cognitive efficiency. Long-term meditation practitioners show structural changes in brain areas involved in cognitive and emotional processing (insula, ACC/MCC, and prefrontal cortex (23)), and mindfulness training changes brain function in these and other areas, with consistent long-term changes in insula cortex. (24, 25) The focused attention involved in mindfulness activates these cognitive networks (26) and even brief mindfulness training improves cognitive efficiency and increases engagement of left DLPFC. (27) Increased cognitive efficiency contributes to control over pain in long-term mindfulness practitioners. (28)

This trial compared enhanced MBSR (MBSR+) to an active control on clinical and imaging outcomes in episodic migraine. We hypothesized that MBSR+ would reduce headache frequency (primary) and reduce migraine-related disability (secondary). We also hypothesized that MBSR+ would alter the structure and function of brain areas and networks involved in cognitive efficiency, including: increased gray matter volume in the DLPFC, MCC, and insula; decreased activation of left DLPFC and cognitive task network (known as the extrinsic mode network (29)) during cognitive challenge; and reduced resting state connectivity from anterior insula to left DLPFC and cognitive task network.

Methods

The study protocol was approved by the Johns Hopkins School of Medicine and the University of Maryland Baltimore Institutional Review Boards. Participants were recruited from local headache clinics, primary care providers, and the community in eight cohorts (9-18 participants/cohort) from June 2014 to February 2017. Recruited individuals were 18 to 65 years of age and met International Classification of Headache Disorders criteria for migraine with or without aura. (30) Eligibility was assessed first by telephone (Figure 1), then a screening visit. Following written informed consent, screening established ≥1 year history of a migraine diagnosis and excluded individuals who reported severe or unstable
psychiatric symptoms, used opioid medications, had prior experience with mindfulness or concurrent treatment expected to affect mindfulness/stress reduction (see Protocol for full inclusion/exclusion). Potential participants completed at least 28 days of an electronic daily diary to establish eligibility (4-14 headache days in 28 days) which served as the baseline measure of headache frequency. Eligible subjects then attended the MRI session, including written informed consent, questionnaires, and quantitative sensory testing.

Assessments

Study questionnaires were completed online at baseline, week 10 (after 8-weeks of MBSR+/SMH), week 20 (after completion of MBSR/SMH), and at week 52. MRI visits at baseline, week 10, and week 20 were conducted by staff masked to treatment group. All MRI scans used a Siemens Tim-Trio 3T MRI scanner with a 32-channel head coil through March 2017, then a Siemens 3T Prisma Fit MRI scanner with a 64-channel head coil (see Appendix Table 1 for details). Scans included a T1 high resolution anatomical scan, a resting state fMRI scan, and fMRI scans during completion of two blocks of painful thermal stimulation and two blocks of cognitive challenge.

Randomization

Randomization (1:1) was stratified by the presence/absence of another chronic pain disorder and headache frequency from the baseline headache diary (low: 4-8; high: 9-14 headache days per 28 days). The randomization schedule was generated online (randomization.com) and stored in a locked cabinet by non-study staff. Assignment occurred by non-study staff when the participant arrived for the first day of class.

Interventions

Participants were instructed to continue stable use of prescribed preventative treatments and continue use of acute abortives as needed. Separate groups for each intervention met for about 2 hours weekly for 8 weeks then bi-weekly for another 8 weeks. A trained expert in the content for each intervention used a manualized protocol that included participant handouts and materials for home use. MBSR+ was administered by 2 experienced, certified instructors (10 and 40 years of meditation experience). SMH was delivered by a nurse practitioner (11 years experience treating headache patients). Checklists were completed by instructors at the end of sessions to verify all components were delivered. Missed sessions were made up individually in person or by phone.

MBSR+ included 2 segments: 1) MBSR included the 8-week program with retreat (32) adapted using trauma-informed methods to include a longer arriving practice at each session and loving kindness in week 2(33); and 2) 4 additional MBSR+ bi-weekly sessions emphasizing self-compassion and including sympathetic joy, equanimity, and gratitude. The final traditional MBSR session focused on applying skills before, during, and after migraines (see Appendix Methods) and the MBSR+ sessions included both didactic content and mindfulness practice, including body scan, yoga, sitting and walking meditations.

SMH included 12 sessions focused on didactic content about the role of stress and other triggers in headaches and followed a similar format and timing to the MBSR+ sessions, minus the retreat. Topics included stress at work and home; coping with stress mental health and personality; sleep hygiene; pain education; and medications for migraine. Information, group discussion, and social support among
group members was emphasized; behavior change and specific skill development was not addressed. Each session included a 10-minute period of standardized muscle stretching exercises.

**Measures**

Sociodemographic and medical data were obtained at baseline (Table 1). Clinical and imaging outcome measures were collected at baseline, week 10 (secondary), and week 20 (primary) and clinical outcome measures were collected at week 52 (secondary). The week 20 time point, along with the 28 day period of prospective diaries that patients completed, conforms to current guidelines on RCTs for migraine prophylaxis(34).

**Primary Outcomes**

**Clinical Outcomes:** The primary outcome was measured as the change from baseline to week 20. Headache frequency was measured using an electronic daily diary for 28 days based on the National Institute of Neurological Disorders and Stroke preventive therapy headache diary, which was provided via an email link. When fewer than the full 28 days were completed, the proportion of headache days was calculated (number of headache days/total number of diary days) and then multiplied by 28 to get a continuous variable for headache days. Note: in the clinical trial registration we included headache-related disability as a primary outcome. However, given prior RCTs on migraine have almost exclusively used headache frequency as the primary outcome, we chose to limit focus on that sole primary outcome.

**Imaging Outcomes:** Brain function was measured as activation during cognitive task(31) performance in left DLPFC and cognitive task network, and resting state connectivity of right dorsal anterior insula to left DLPFC and cognitive task network. Brain structure was measured as gray matter volume in DLPFC, cingulate, and anterior insula. Regions-of-interest were defined from the cognitive task group activation map for all participants combined at baseline. Peak voxels for each region were selected, a 4mm radius sphere was created, and data were extracted from the scan of interest for each subject.

**Secondary outcomes**

**Clinical Outcomes:** Secondary outcomes were assessed at weeks 10, 20, and 52. Headache-related disability was measured using the six item Headache Impact Test(35) that shows strong psychometric properties.(36) Headache intensity was computed as the average of all headache intensity ratings from the electronic daily diary.(34) Response to treatment was defined as >50% reduction in number of headache days(34) from baseline to week 20. A migraine(31) day was coded when at least 2 of the following criteria were met: unilateral, pulsating, moderate/severe pain, aggravated by routine activity; and at least one of the following criteria were met: nausea/vomiting or light/noise sensitivity

**Imaging Outcomes:** Whole brain analyses of gray matter volume, activation to pain, activation to cognitive challenge, and resting state connectivity of the insula cortex were measured using Sandwich estimator toolbox(37) (see Appendix).

**Sample size**

Using a 0.050 two-sided significance level, a sample of 90 subjects randomized to 2 treatment groups (1:1) provides 80% power to detect an effect size of at least 0.60 in change of headache frequency for
MBSR+ relative to SMH using a t-test and the difference between a proportion of responders for MBSR of 0.435 (20/45) and for SMH of 0.150 (7/45) using a Fisher's exact test.

Statistical Methods

Clinical outcomes were analyzed using the intention-to-treat approach. Effects of intervention were estimated using mixed-effects models, where patient was a random effect, and fixed factors included treatment, time, treatment-by-time interaction, age, cohort, interval in days between MRI and treatment, medication, presence of other pain, and education. Difference in treatment response rate was assessed using a generalized linear model with a logit link function. The regression model for the mean with the binomial distribution variance function was utilized to model the log odds ratios. The generalized linear models included the following covariates: age, medication, level of education, presence of other pain, interval in days between MRI and first intervention. A logistic regression model predicted probability of response to treatment. P-values are nominal and not adjusted for multiple outcomes. Testing was two-sided and used the 0.05 level of significance, and statistical analyses used RStudio, Version 1.1.453.

Imaging outcomes were analyzed per protocol and additional exclusion criteria for MRI data, sequence information, data preprocessing, and first level analyses are described in Appendix. Linear mixed models included patient as a random effect and fixed factors of treatment, time, and the treatment-by-time interaction, and scanner as a covariate, with bonferroni correction for multiple comparisons. The Sandwich estimator toolbox(37) modeled longitudinal changes in whole brain analyses. Statistical significance was assessed using 10,000 iterations of wild bootstrap, and cluster-based correction for multiple comparisons using a familywise error rate alpha of 0.05, with a cluster-forming threshold of p<0.001. The contrast of interest was the treatment-by-time interaction. Main effects of time and treatment are provided in Appendix.

Results

Among 573 individuals contacted for telephone screening, 168 were potentially eligible and 119 of these met the headache frequency criteria during baseline (Figure 1). The main reasons for exclusion were not meeting migraine or headache frequency criteria, ineligible or refused MRI/pain testing, schedule incompatibility, or migraine secondary to injury. Ninety eight participants were randomized to treatment; 50 were assigned to receive MBSR+ and 48 were assigned to receive SMH. All attended at least one session. Five participants (5%) withdrew from treatment after the first session but agreed to continue with data collection and 3 participants (3%) withdrew from treatment and were lost to follow-up. Forty three (86%) of the MBSR+ participants and 40 (83%) of the SMH participants completed all sessions, either in the group or individually as a make-up.

At baseline, treatment groups were similar on all sociodemographic characteristics (Table 1). Participants (mean age of 36 years) were predominantly female (91%), white (72%), and 80% had completed at least one year of college. At baseline, they reported an average of 7.8 headache days and only 15% were using a preventive treatment for migraine. There were no group differences in treatment withdrawal or loss to follow-up.

Primary outcomes
At week 20, the MBSR+ group reported fewer headache days (4.6 [95% CI 3.6 to 5.6]) compared to the SMH group (6.0 [95% CI 4.9 to 7.0]; \( P = .04 \); Table 2). This effect was apparent at week 10, as the MBSR+ group reported fewer headache days (5.5 [95% CI 4.6 to 6.5]) compared to the SMH group (6.9 [95% CI 5.9 to 7.9] \( P = .04 \)). This treatment effect was not significant at week 52 (\( P = .12 \)).

Regions of interest revealed no significant treatment-by-time effects related to gray matter volume, cognitive task activation, or resting state fMRI (Figure 3 and Appendix). Both groups showed decreased anterior mid cingulate volume (\( P = .04 \)) and decreased connectivity of right dorsal anterior insula to cognitive task network (\( P = .02 \)) at week 20.

**Secondary outcomes**

At week 20, the MBSR+ group also reported reduced HIT-6 scores (2.0 [95% CI 1.1 to 2.9]) compared to the SMH group (3.7 [95% CI 2.7 to 4.7]; \( P = .04 \)). Headache impact did not differ between treatment groups at week 10 or week 52 (Table 2) and average headache pain intensity did not differ between treatment group at any timepoint (Table 2). At week 20, 52% of the MBSR+ group were classified as treatment responders (\( \geq 50\% \) reduction in headache days) compared to 23% of the SMH group (\( P = 0.004; \) Table 2, Figure 2), yielding a number needed to treat (NNT) of 3.4. The MBSR+ group reported fewer migraine days at week 10 (\( P = .0008 \)) and week 20 (\( P = .004 \)) relative to SMH, but not at week 52 (Table 2).

Whole brain analyses revealed a significant treatment-by-time interaction on activation during the cognitive challenge. The MBSR+ group showed decreased activation in the bilateral cuneus and right parietal operculum at week 20 compared to the SMH group (Appendix Table 2). Whole brain analyses also revealed a significant interaction of left dorsal anterior insula connectivity to the right posterior parietal cortex and right cuneus (Appendix Table 2). There were no significant interaction effects for the other five insula seed regions, gray matter volume, or activation during pain stimulation for the whole brain analyses.

**Adverse Events**

There were 16 adverse events reported of which 15 were mild (e.g., high blood pressure, hives, jaw pain) or moderate (e.g., car accident, kidney stone); the one serious adverse event (stroke), in accordance with the data safety monitoring plan and consultation with the independent monitoring committee, was deemed unlikely related to intervention. The remaining 7 were definitely not related, 7 were unlikely related, and 1 was possibly related to study procedures (one participant reported a migraine during the MRI session).

**Discussion:**

Among adults with episodic migraine, enhanced mindfulness based stress reduction (MBSR+) decreased headache days and headache related disability, as well as yielded a higher treatment response rate, relative to the active control (SMH). Treatment response (50% reduction in headache frequency) to MBSR+ relative to SMH yielded an NNT of 3.4, which is comparable to valproic acid – one of the first line treatments for episodic migraine prophylaxis. (38) These results hold promise for the use of mindfulness-based interventions for headache, with treatment response rates qualitatively comparable or exceeding effects of most existing standard pharmaceutical therapies in the time frames they have been tested. (39-53) Developing and testing methods to sustain these benefits over longer periods is...
significant reductions in headache frequency did not sustain over the 52 week follow-up.

Although no effects of MBSR+ training were observed on the primary neuroimaging outcomes, secondary whole-brain analyses identified two findings that suggest an increase in cognitive efficiency. Compared to SMH, MBSR+ training led to decreased activation of the parietal operculum and visual cortex (cuneus) during the cognitive challenge. Both long-term meditators (55) and individuals trained in MBSR (56) show altered visual cortex connectivity and increased activation during focused attention. The parietal operculum, including posterior insula, is activated by pain and deactivated by cognitive challenge (57) and we have previously reported that this is the only acute pain-related activation that is modulated by cognitive demand in both healthy subjects and migraine patients. (21) Additionally, we observed reduced resting connectivity of the dorsal anterior insula to posterior parietal cortex and visual cortex (cuneus) following MBSR+ training compared to SMH. Because dorsal anterior insula strongly connects to the posterior parietal cortex and cuneus as part of the cognitive task network, (58) this finding supports increased cognitive efficiency following MBSR+. These increases in cognitive efficiency seen in the MBSR+ group may reflect changes due to the practice of meditation or alternatively may reflect the effect of having fewer headaches during the period surrounding measurement.

This is the first study to our knowledge using MRI primary outcomes in a registered clinical trial for a chronic pain condition. The primary imaging outcomes, including changes in gray matter volume, activation during cognitive challenge, and resting state connectivity of the anterior insula in a priori selected regions-of-interest, did not differ between groups. The choice of these regions was based on literature when the study was proposed and our preliminary data, focusing on the DLPFC (59) and other brain areas showing pain-cognition interactions. (21, 60-64) The vast majority of neuroimaging studies compare individuals with chronic pain to healthy subjects, rather than longitudinal designs examining how the brain changes with treatment. Since we did not find treatment effects in the areas that distinguish those experiencing daily pain, our findings suggest that brain changes distinguishing patients from healthy controls might not be useful as treatment targets.

Most MRI studies reporting effects of treatment have only investigated the treatment group, (64-67) or treatment responders within a group exposed to treatment, (68-70) and ours is the first study to compare two active treatment arms and including both treatment responders and nonresponders. It is possible that the results from previous studies examining brain changes over time are dependent on treatment response, rather than the effects of intervention itself. Future work should thus include comparisons of responders and non-responders.

The present findings share limitations common to most RCTs and may have limited generalizability due to the likely selection bias that results from the strenuous requirements of participation, including time commitment and willingness to complete repeated MRI scans, resulting in most of the participants being college educated. Study strengths, in addition to the use of MRI outcomes, include one of the largest sample sizes for measuring brain imaging outcomes in migraine or any chronic pain disorder, the very small loss to follow-up, the close matching of MBSR+ to the active control, and long-term follow-up.

**Conclusions:**

In episodic migraine, MBSR+ showed superior treatment effects compared to an active control, with significant reductions in headache frequency that are comparable to commonly used first line
treatments for episodic migraine prophylaxis. Brain changes in the MBSR+ group were seen in the pattern of functional connectivity and activation during a challenging cognitive task that are consistent with increased cognitive efficiency. These findings suggest that MBSR+ can be an effective prophylactic treatment option for episodic migraine.

<sup>1</sup>Primary clinical outcome time point was week 20 (gray shading).

<sup>2</sup>adjusted for cohort, age, medication, and education level.

<sup>3</sup>adjusted for cohort, age, medication, and presence of idiopathic pain.

<sup>4</sup>adjusted for cohort, age, medications, education level, presence of idiopathic pain, and interval days between baseline and first MBSR/SMH session.

<sup>5</sup>Response was defined as 50% or greater reduction in headache frequency at week 20 compared to baseline.
Figure 1. Participant Flow Through Trial Comparing Extended Mindfulness Based Stress Reduction and Stress Management for Migraine Headache.

a – Of the 50 participants randomized to receive extended mindfulness-based stress reduction, 43 completed all 12 sessions. Participants were recruited in 8 separate cohorts (range of 4-8/cohort).

b – Of the 48 participants randomized to receive stress management for headaches, 40 completed all 12 sessions. Participants were recruited in 8 separate cohorts (range of 2-11/cohort).
Figure 2. Clinical outcomes. Mean (thick lines; 95% confidence intervals shown in thin lines) number of headache days per 28-day diary (uncorrected values) for SMH (gray) and MBSR+ (black). Responder rates (with response defined as a 50% reduction in headache days from baseline) are shown in bar plots, with MBSR+ in red and SMH in blue. At week 20 (primary outcome) both headache frequency and response rate were significantly better in the MBSR+ group.

Figure 3. MRI outcomes. A) Regions-of-interest for primary outcome analyses, defined from the baseline group map (all patients) for activation during the cognitive task. There were no significant effects of treatment for region-of-interest analyses. B) whole-brain analysis interaction effect for cognitive task-related activation. Identified regions show a decrease in activation level in the MBSR+ compared to SMH group over time. C) whole-brain analysis interaction effect for left dorsal aINS connectivity. Regions show a decrease in activation level in the MBSR compared to SMH group over time. Images are displayed on the average anatomical MRI for all patients at baseline. Error bars are 95% confidence intervals.
