Abstract

Chronic inflammation might contribute to the development of amyotrophic lateral sclerosis (ALS). The relationship between serum immunoglobulins and risk of ALS remains however greatly unknown. In order to overcome limitations like reverse causation and residual confounding commonly seen in observational studies, we applied polygenic risk score (PRS) and Mendelian randomization (MR) analyses on summary statistics from the large-scale genome-wide association studies (GWAS), to examine the polygenic and causal associations between three serum immunoglobulins (IgA, IgM, and IgG) and risk of ALS (first in a discovery phase and then in a replication phase). An inverse polygenic association was discovered between IgA and ALS as well as between IgM and ALS. Such associations were however not replicated using a larger ALS GWAS and no causal association was observed for either IgA-ALS or IgM-ALS. A positive polygenic association was both discovered [odds ratio (OR) = 1.18; 95% confidence interval (CI): 1.12-1.25, P=5.9×10^{-7}] and replicated (OR=1.13, 95% CI: 1.06-1.20, P=0.001) between IgG and ALS. A causal association between IgG and ALS was also suggested in both the discovery (OR=1.06, 95% CI: 1.02-1.10, P=0.009) and replication (OR=1.07, 95% CI: 0.90-1.24, P=0.420) analyses, although the latter was not statistically significant. This study suggests a shared polygenic risk between serum IgG (as a biomarker for chronic inflammation) and ALS.
Introduction

Amyotrophic lateral sclerosis (ALS) is a relatively rare but fatal neurodegenerative disease. Chronic inflammation and altered immune responses have been suggested to contribute to the pathogenesis of ALS.\(^1\)\(^,\)\(^2\) The relationship between serum immunoglobulins, as known biomarkers for inflammation and immune responses, and risk of ALS remains however greatly unknown. In a previous study, we did not find a statistically significant positive association between immunoglobulin G (IgG) and risk of ALS [hazard ratio=1.04; 95% confidence interval (CI): 0.89-1.22; per 2.99 g/L increase of IgG].\(^3\) In the same study, we found also that during the 20 years before diagnosis, patients with ALS had more rapidly declining levels of IgG compared to others.\(^3\) We speculate that the noted lack of association between IgG and ALS might be attributable to both a real positive association between IgG and ALS (i.e., higher levels of IgG lead to higher risk of ALS) and reverse causation (i.e., ALS results in declined levels of IgG). In addition to reverse causation, observational studies are also prone to other systemic errors, which collectively make it often difficult to infer causality for associations noted in observational studies.\(^4\)

By using the summary statistics from large-scale genome-wide association studies (GWAS), polygenic risk score (PRS) and Mendelian randomization (MR) analyses have added novel evidence to support polygenic and causal relationships between several traits and ALS, corroborating importantly findings from previous observational studies.\(^5\)\^-\(^7\) In this study, we aimed to examine the polygenic association and infer the causality between IgG and risk of ALS, using summary statistics from GWAS of serum immunoglobulins and ALS. Because IgG is a biomarker for chronic inflammation, we hypothesized that there is a positive and causal relationship between IgG and ALS. We additionally studied another two serum immunoglobulins (IgA and IgM) to assess the specificity of the IgG result. The roles of these two biomarkers have rarely been studied in ALS.
Materials and Methods

Summary statistics

We used publicly available summary statistics of several GWAS within the European ancestry population in this study. GWAS of serum immunoglobulins (IgA, IgM, and IgG) were conducted among ~15000 individuals, from which single nucleotide polymorphisms (SNPs) with the association P-values <1.0 × 10^{-6} were available. GWAS summary statistics of ALS were obtained from two studies (available in the IEU GWAS database; https://gwas.mrcieu.ac.uk, ID for ALS_2016: ieu-a-1085; ID for ALS_2018: ebi-a-GCST005647). In the discovery analysis, summary statistics of ALS (ALS_2016) were obtained from a GWAS performed among 36052 individuals (including 12577 patients with ALS and 23475 controls) by the Project MinE group. In the replication analysis, summary statistics of ALS (ALS_2018) were obtained from a meta-analysis incorporating the results from ALS_2016 and another GWAS including 44558 individuals (8229 patients with ALS and 32369 controls).

Using IgA, IgM, and IgG as the exposures (base traits) and ALS as the outcome (target trait), the polygenic and causal associations of six exposure-outcome pairs (three in the discovery analysis and three in the replication analysis) were investigated by PRS and MR analyses, respectively. Because the values of immunoglobulins were standardized in the GWAS, we estimated accordingly odds ratio (OR) per standard deviation of genetically determined level for each type of immunoglobulin in the present study.

PRS analyses

Polygenic associations were investigated by PRS analyses in Linux with PRSice package (version 1.25). For the summary statistics of each exposure, correlated SNPs were pruned by linkage
disequilibrium (LD) clumping with default parameter settings. Genotypes of the HapMap_ceu_all (release 22, 60 individuals, 3.96 million SNPs) were used as the reference panel, clumping threshold p1=p2=0.5, LD threshold r²=0.05, and the distance threshold of 300Kb. Independent SNPs were then extracted and included in 100000 quantiles with gradually increasing P-value thresholds (PT, ranging from 0 to 1.0×10⁻⁶, in steps of 1.0×10⁻¹¹ per quantile). The PT of the quantile that explained the largest variance of the target was defined as the best-fitted PT.

**MR analyses**

Causal inferences were performed by MR analyses in R (version 3.6.1) with TwoSampleMR package (version 0.5.2). Lead SNPs from the genetic loci reported to be associated with each exposure were extracted from the GWAS of immunoglobulins. The associations of the SNPs with other traits (associations with a P-value <5×10⁻⁸) were checked in GWAS Catalog (https://www.ebi.ac.uk/gwas) and excluded, leaving independent lead SNPs after LD clumping as the instrumental variables (IVs, Supplementary Table 1). The causal relationship of each exposure-outcome pair was primarily examined by the inverse variance weighted (IVW) method and complemented with another four methods (MR Egger regression, weighted median, simple and weighted mode) as sensitivity analyses.

**Results**

Inverse polygenic associations were discovered for IgA-ALS and IgM-ALS (Table 1). Neither of the associations was however replicated (Supplementary Figures 1-2). A positive polygenic association between IgG and ALS was found both in the discovery and replication analyses (Supplementary
Figure 3). The OR was 1.18 (95% CI: 1.12-1.25, P=5.9×10^{-7}) in the discovery analysis and 1.13 (95% CI: 1.06-1.20, P=0.001) in the replication analysis.

In the MR analyses, causal association was not found for either IgA-ALS or IgM-ALS (Table 2), regardless of the use of MR methods (Supplementary Table 2 and Supplementary Figures 4-5). For IgG-ALS, a statistically significant causal association was found in the discovery analysis (OR=1.06, 95% CI: 1.02-1.10, P=0.009). A causal positive association was also suggested in the replication analysis, although not statistically significant (OR=1.07, 95% CI: 0.90-1.24, P=0.420).

Discussion

Utilizing PRS and MR analyses of large-scale GWAS of immunoglobulins and ALS, we provided new evidence supporting a potentially causal positive association between IgG, but not IgA or IgM, and risk of ALS.

Accumulating evidence supports that inflammation and altered immune responses are involved in the different phases of ALS.\textsuperscript{13} Physiological barriers (e.g., blood-brain barrier) and innate immunity cells (e.g., macrophages) are fundamental in the maintenance and modulation of the central nervous system, whereas chronic inflammation might lead to dysfunction of the neurons.\textsuperscript{14} B cells play important roles in adaptive immunity, through producing immunoglobulins and presenting antigens to T cells.\textsuperscript{15} IgA constitutes 10-20\% of serum immunoglobulins and is mainly involved in the mucosal immune response. IgM constitutes 5-10\% of serum immunoglobulins and is the earliest released antibody during adaptive immune response. IgG constitutes ~75\% of serum immunoglobulins and can be transmitted through placental and blood-brain barriers.\textsuperscript{16} Few studies have however examined the roles of these immunoglobulins in ALS to our knowledge. In our
previous cohort study including more than half a million participants with >20 years of follow-up, we found that per 2.99 g/L increase of IgG levels in blood, there was a 4% increased risk of ALS, although the association was not statistically significant. The lack of statistical significance might be multifactorial, including first a potentially real positive association between IgG and ALS risk, a lack of statistical power due to the relatively small number of ALS cases identified (N=152), and also reverse causation (i.e., patients with ALS had more rapidly declining IgG levels, compared to individuals not developing ALS, during the 20 years before ALS diagnosis).

By using summary statistics from several large-scale GWAS, in the present study, we identified a statistically significant positive polygenic association between IgG and ALS in both the discovery and replication analyses. The association is further suggested to be causal in the MR analysis. Although statistically significant result was only obtained in the discovery analysis, similar point estimate was noted in the replication analysis. The differences between the discovery (ALS_2016) and replication (ALS_2018) samples might have contributed to the lack of statistical significance in the replication analysis. For instance, in the discovery GWAS (ALS_2016), patients with ALS and controls were matched for age, sex, and geographic regions, whereas in the replication GWAS (ALS_2018) >50% of participants were only matched for race/ethnicity. In contrast to IgG, no clear polygenic association nor causal relationship was noted for IgA-ALS and IgM-ALS. This different result pattern might be partly explained by the fact that IgG is a biomarker for chronic inflammation and bypasses the blood-brain-barrier, which might be more relevant for neurodegenerative diseases including ALS, compared to the other immunoglobulins.

Causal inference by MR analysis requires three basic assumptions: 1) relevance, i.e., IVs have causal effects on the exposure such as IgG; 2) exclusion restriction, i.e., IVs affect the outcome, such as ALS, only through the exposure; and 3) exchangeability or independence, i.e., no common
causes between IVs and the outcome. Even though we used the latest and largest GWAS of immunoglobulins, only two independent SNPs could be selected as IVs for IgG. As a result, we could only use IVW methods in the MR analysis. According to the current GWAS Catalog, no genome-wide significant association was identified between the two IVs of IgG and other non-ALS traits. Interestingly, the two genes near these two IVs (FCGR2B near rs7554873 and HLA-DQB1 near rs2133037) are both biologically related to immune responses, neuroinflammation, and neurodegeneration.

In conclusion, our study suggests a shared polygenic risk between serum IgG and ALS. The causality between IgG and ALS needs to be further validated when more instrumental variables are available and when different methods of causal inference are possible to use.

Acknowledgment

The authors would like to thank the Project MinE group and the ALS Variant Server for sharing the summary statistics of GWAS on ALS. This project is partly supported by the Swedish Research Council (Grant No.: 2019-01088) and Karolinska Institutet (Senior Researcher Award and Strategic Research Area in Epidemiology).
