Abstract:

SARS-CoV-2 infection has the potential for targeting central nervous system and several neurological symptoms have been described in patients with severe respiratory distress. Here we described the case of an otherwise healthy 60-year old subject with SARS-CoV-2 infection but only mild respiratory abnormalities who developed severe progressive encephalopathy associated with mild pleocytosis and hyperproteinorrachia. MRI was negative whereas EEG showed theta waves on the anterior brain regions. Serum and CSF analyses excluded other known infectious or autoimmune disorders. The patient dramatically improved after high-doses steroid treatment suggesting an inflammatory-mediated brain involvement related to SARS-CoV-2 infection.
Introduction

Coronavirus disease 2019 (SARS-CoV-2) is characterized by respiratory tract symptoms with possible severe outcome mostly related to pneumonia and acute respiratory distress syndrome\(^1\). Data regarding specific neurological involvement due to SARS-CoV-2 (COVID-19) infections are lacking. Neurological symptoms including headache and delirium have been described in epidemiological studies up to 30% of patients\(^2\). Although previous coronavirus infections have been associated to involvement of central nervous-system (CNS)\(^3\), the neurotropism of COVID-19 is still theme of debate\(^4\text{-}^6\).

The present report describes a case of severe encephalopathy in a patient with COVID-19. During his hospitalization, he never developed severe acute respiratory syndrome (SARS) but mild respiratory symptoms. The patient provided an informed written consent for the report and the diagnostic /therapeutic procedures were conducted in accordance with institutional and international guidelines for protection of human subjects.

Case description

An otherwise healthy 60-year-old man presented to the Emergency Department for a severe alteration of consciousness. According to the relatives, the symptoms started five days earlier with the development of progressive irritability, confusion and asthenia followed two days later by fever, cough and cognitive fluctuations. At admission, his vital parameters were within the normal ranges and his body temperature was 36,8 °C. Oxygen saturation was within normal limits with a slight reduction of the arterial partial pressure of oxygen (Sp02 73 mmHg).
The patient displayed an akinetic mutism with a wakeful state of profound apathy; he was able to follow the examiner with the eyes but unable to carry out even simple orders. Beside positive palmomental and glabella reflexes with moderate nuchal rigidity, the neurological examination was normal.

Blood analyses revealed normal blood cell counts, increased D-dimer (968 ng/mL) but normal levels of CRP, fibrinogen and ferritin. Chest x-ray showed moderate bilateral interstitial pneumonia. Based on the history, the radiological findings and COVID-19 outbreak in the region, a real-time reverse transcriptase-polymerase chain reaction assays (RT-PCR) on nasopharyngeal swab was performed and confirmed a SARS-CoV-2 infection. Antiviral therapy with Lopinavir/Ritonavir 400/100 mg BID and hydroxychloroquine 200 mg BID was started.

A brain CT scan was unremarkable, and the patient was hospitalized. At admission, a lumbar puncture was performed, and CSF showed inflammatory findings with mild lymphocytic pleocytosis (18/uL) and moderate increase of CSF protein (696 mg/dL). The analysis of neurotropic viruses (HSV-1, HSV-2, HSV-6, HSV-8, EBV, VZV and Adenovirus) was negative. CSF RT-PCR for SARS-CoV-2 was also negative. An electroencephalography (EEG) exhibited a generalized slowing, more prominent on the anterior regions with decreased reactivity to acoustic stimuli (Figure 1). The same day an empirical treatment of ampicillin and acyclovir was introduced. The day after, a Brain Magnetic Resonance imaging (MRI) with Gadolinium did not reveal significant alterations or contrast-enhanced areas within brain and/or meninges (Figure 1). Three days after admission, given the persistence of clinical symptoms, a high intravenous steroid treatment was started (methylprednisolone 1 g/day for five days). CSF analyses, carried out one day after steroids administration, showed lymphocytic pleocytosis (18/uL), hyperproteinorrachia (1272 mg/dL) and normal Link index without oligoclonal bands. CSF RT-PCR for SARS-CoV-2 was still negative.

The clinical response to steroid therapy was quite impressive. The day after the first infusion, the clinical conditions of the patient improved, and he became alert; he was able to execute simple tasks proposed by examiner and to repeat single words. The following days, the patient was able to talk
and to answer to simple questions. Once the five days-high dose steroid therapy ended, he displayed only mild disinhibition and still fluctuating alertness.

A follow-up MRI nine days after admission was normal while serial EEG revealed improvement and normalization of anterior regions slowness (Figure 1, D). A wide immunological screening of immune-mediated encephalitis (NMDAR, LGI1, CASPR2, GABA$_A$R, GABA$_B$R and AMPAR, Ri, Yo, Ma2, Hu, Amphiphysin) was negative as well as anti-MOG antibodies (Supplementary details). Ten days after the admission, there was an improvement of CSF protein (914 mg/dL) but still lymphocytic pleocytosis (38 cells/uL). Oral prednisone was thus started with progressive tapering. At discharge, eleven days after admission, the patients presented with normal neurological examination.

Discussion

The potential neurotropism of COVID-19 with direct or autoimmune-mediated response is still debated$^{4-6,7}$. We here described a case of steroid-responsive encephalopathy in a patient with confirmed COVID-19 infection.

After the first reports describing severe pneumonia cases in Wuhan, China, COVID-19 rapidly spread worldwide with critical challenges for the health care systems all over the world$^{8,9}$. The World Health Organization has thus declared COVID-19 a public health emergency of international concern, with a global estimate of 1.153.287 cases and 61.663 deaths on the 4$^{th}$ of April. Brescia, situated in Lombardy region, northern Italy was one of the province more affected by COVID-19 accounting for more the 9,000 cases on the 4$^{th}$ of April 2020.

Epidemiological studies showed that COVID-19 disease presents in the large majority of cases with fever and upper respiratory symptoms$^2$. Recently, a study posted in medRxiv$^4$ and still unpublished has reported neurological manifestations in COVID-19 in the outbreak in China in up to 36.4% of patients hospitalized, including alteration of consciousness, headache, dizziness and delirium$^6$. 
Neurological manifestations were also reported in previous epidemiological studies on larger samples\(^2\). The CNS-potential diffusivity by blood or nasal-pharyngeal route, supported by in vitro-models as already described for similar viral agents, is still questioned for COVID-19. Further support for the hypothesis of nasal-pharyngeal route is provided by clinical observations of frequent and persistent anosmia/dysgeusia in COVID-19 infected subjects.

Several authors reported neurological symptoms in severe cases, supporting the concept that CNS symptoms might be secondary to severe respiratory failure\(^7\).

Another important aspect is the hyperinflammation state secondary to COVID-19 infection, with massive release of cytokines and chemokines that could alter the permeability of blood-brain barrier (BBB). This phenomenon could indeed cause the activation of the neuroinflammation cascade\(^5\). Hypothetically, COVID-19 could also induce, by molecular mimicry related mechanisms, the production of antibodies against neural or glial cells, as demonstrated for HSV-1, EBV or Japanese encephalitis\(^10-12\).

The here described COVID-19 case is of particular interest, as the patients presented with severe encephalopathy with only mild respiratory alterations. Meningeal signs at presentation were suggestive for meningoencephalitis and the patient started combined antibiotic and antiviral treatment, according to current guidelines for CNS-infections\(^13\). Lack of presence of COVID-19 in two different CSF samples analyses could not definitely exclude the diffusion into the CNS, as viruses could enter in CSF and be cleared from it by the time of illness onset, such as in the case of West-Nile virus\(^14\). In our case, the blood brain barrier alterations supported by CSF analyses argue for a potential CNS invasion via blood route of COVID-19\(^3\). Of interest, peculiar akinetic mutism presentation has been associated with cases of Epstein-Barr encephalitis\(^15\). However, the normal MRI findings, with no meningeal enhancement or brain alterations, and the response to steroid treatment support other alternative pathophysiological mechanisms. In this case, we excluded the most common causes of autoimmune encephalitis, akinetic mutism and psychosis so far\(^16-18\).
Another possible explanation of transitory akinetic mutism would be an abnormal neuroinflammation response induced by COVID-19, already associated with akinetic mutism in adult onset Still syndrome. This hypothesis better fit with the short time relationship with COVID-19 infection and with the prompt response to steroid treatment.

**Conclusions**

The case highlighted that COVID-19 may cause severe neurological alterations independently from respiratory function. Despite the unclear pathophysiology, the impressive response to steroid treatment pointed out a possible autoimmune or hyperinflammatory-mediated mechanism but did not exclude a direct CNS-diffusion of COVID-19. The report highlighted the importance for larger studies evaluating neurological manifestations of COVID-19 in order to find out the best management strategies of this growing disease worldwide.
