Abstract

Background: Environmental factors, including air pollution, can strongly impact on spatio-temporal patterns of infectious diseases outbreak. In this study, we aimed to investigate the association and correlation between ambient air pollutants and case fatality rate (CFR) of the novel coronavirus disease (COVID-19) in China.

Methods: Publicly accessible data on COVID-19 average CFR were utilized in the data analysis. The ambient daily air pollutants including fine particulate matter (PM₂.₅), inhalable particles (PM₁₀) and nitrogen dioxide (NO₂) during the period from December 25, 2019 to March 5, 2020 were obtained from National Air Quality Real-time Publishing System of China. Ecological analysis was performed to explore
the association and correlation between the cumulative average exposure of ambient
air pollutants at different lag days (14 and 28 days) and average CFR in China outside
Hubei and cities in Hubei province via model fitting.

Results: The average case fatality rate was highest in Wuhan city (4.53%) and the
cumulative average exposure of ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ at lag 28 days was
55.8±12.1$\mu$g/m$^3$, 66.8±9.2$\mu$g/m$^3$, 20.7±4.4$\mu$g/m$^3$, respectively in Hubei province
during the study period. Ecological analysis showed that ambient PM$_{2.5}$, PM$_{10}$ and
NO$_2$ exposure at both lag 14 and 28 days was positively correlated with average CFR
in China outside Hubei (province-level). For city-level analysis in Hubei, significant
associations were only found between cumulative ambient NO$_2$ exposure and average
CFR (r=0.693 for Lag0-14, r=0.697 for Lag0-28, respectively) during the same period.

Conclusion: Our findings suggested ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ exposure,
especially at 28 lag days, positively associated with the case fatality rate of
COVID-19 in China. These results could help provide guidance for identifying
potential exposure window and preventing and controlling the epidemic.

Keywords: COVID-19; Air pollution; Case fatality rate; Ecological study; China
The novel coronavirus disease (COVID-19) is an ongoing global epidemic event, which caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[1]. Respiratory droplets and human-to-human contact are the major routes of transmission of COVID-19. Some studies showed that environmental factors might influence the transmissions and risk of COVID-19[2, 3]. Since COVID-19 is a respiratory infectious disease and SARS-CoV-2 could remain viable in aerosols for hours [4], it’s interesting to investigate the associations between air pollution and COVID-19 infection, and identify possible indicator of air pollutants for blocking the epidemic. However, the study on the effects of air pollutants on the death risk of COVID-19 infection was still limited and inconsistent in China. In this study, we aimed to investigate the associations between ambient air pollutants exposure and case fatality rate (CFR) of COVID-19 in Mainland China, to provide scientific guidance for identifying potential exposure time window and preventing and controlling the epidemic.

Methods

For this multi-city ecological study, we collected the daily cumulative confirmed and death numbers of COVID-19 cases information in China during the study period from January 22 to March 5, 2020 from the National Health Commissions (http://www.nhc.gov.cn/xcs/xxgzb/index.shtml) and provincial Health Commissions of China (http://wjw.hubei.gov.cn/bmdt/ztzl/fkxxgzb/index.shtml). Due on no death case was reported in 5 provinces (Xizang, Qinghai, Shanxi, Jiangsu and Ningxia) by March 5, 2020 and island-province factor (Hainan), a total of 25 provinces covering 256 cities (243 cities outside Hubei, 13 main cities in Hubei) were included in our study. The average case fatality rate of COVID-19 was calculated in China outside Hubei at province-level, and in each city of Hubei province during the same period. Due on the data were all from public websites, the Ethical approval was not needed in the study.
The data on daily average concentrations of air pollutants including fine particulate matter (PM$_{2.5}$), inhalable particles (PM$_{10}$) and nitrogen dioxide (NO$_2$) during the period from December 25, 2019 to March 5, 2020 was obtained from National Air Quality Real-time Publishing System of China. This platform provided the real-time criteria air pollutants in all state-controlled monitoring stations. To control for the potential confounders, the ambient daily average temperature, relative humidity for each city was obtained from China Meteorological Data Service Center (http://data.cma.cn/en).

The temporal cumulative average exposure of ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ at different lag days (14 days and 28 days) before the daily case reports was evaluated among the cities in Hubei province (city-level) and in China outside Hubei (province-level).

Ecological analysis was conducted to explore the temporal associations between the cumulative average exposure of ambient air pollutants and COVID-19 case fatality rates in China outside Hubei (province-level) and in Hubei province (city-level). Multiple regression models were fitted to the data among 24 provinces of China and city-level analysis in Hubei province alone during the study period.

Results

Among the cities in Hubei province, the cumulative average exposure level of the ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ at lag 28 days was $55.8\pm 12.1 \mu g/m^3$, $66.8\pm 9.2 \mu g/m^3$, $20.7\pm 4.4 \mu g/m^3$, respectively during the study period. The average case fatality rate was highest in Wuhan city (4.53%), followed by Jingmen city and Ezhou city in Hubei province during the study period. For provinces outside Hubei, the average CFR was highest in Heilongjiang province and lowest in Zhejiang province of China.

The linear regression analysis showed a positive association between air pollutants exposure and average case fatality rate in China. As indicted in Figure 2, the associations are all significant between average CFR and cumulative average exposure to ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ in both lag 14 and 28 days at province-level in China outside Hubei. The correlation coefficient of NO$_2$ was highest
(r=0.739, P<0.001) among the three air pollutants at lag 28 days (Figure 2). For Hubei province, city-level analysis showed a positive association between cumulative average exposure of NO$_2$ and average CFR (r=0.693 for Lag0-14, r=0.697 for Lag0-28, respectively), while no significant associations were observed between ambient PM$_{2.5}$ and PM$_{10}$ exposure and average CFR in cities of Hubei province.

**Discussion**

Our study suggested that ambient particulate matter and NO$_2$ exposure was associated with the increased case fatality of COVID-19 in Mainland China. These findings could provide evidence that air pollution is an important factor in COVID-19 infections.

Previous studies has indicated that air pollution associated with a variety of respiratory disease including SARS, influenza, asthma and COPD[5-8]. A recent time-series study showed that ambient particulate matter, NO$_2$ exposure was associated with the increased confirmed case number of COVID-19[9]. A study conducted in multiply countries indicated that long-term exposure to ambient NO$_2$ could be a contributor factor to COVID-19 fatality[10]. Consistent with prior studies, our results indicate ambient NO$_2$ exposure, especially at 28 lag days, might increase the CFR of COVID-19. The biological explanation might be that air pollutants could compromise lung function and increase COVID-19 fatality[8].

To our knowledge, this was one of the few studies performed in Chinese cities to explore the temporal associations between ambient air pollutants exposure and case fatality rate of COVID-19. The high correlation between ambient NO$_2$ and CFR of COVID-19, especially at 28 lag days exposure, might help identifying which pollutants in certain exposure time window play the dominate role in increasing the death risk of COVID-19 in China.

However, our study has some limitations. First, ecological study designs were adopted in the study, other city-level factors including implementation ability of control policy of COVID-19, the availability of medical resources might confound our findings. Second, the study period may not represent a whole air pollutants pattern.
associated with the average case fatality rate of COVID-19. Furthermore, the exposure misclassification might bias the study result due to the different activity patterns of people. For all these limitations, the findings should be interpreted with caution before extension to other population and research.

Conclusions
Our study suggest positive associations between ambient PM$_{2.5}$, PM$_{10}$ and NO$_2$ exposure and case fatality rate of COVID-19 in China. The 28-day lag effects of air pollutants can help to identify the potential exposure window that have the high adverse impact on the COVID-19 and improve the public practice for preventing the epidemic.
