Abstract — Pandemics including COVID-19 have disproportionately affected socioeconomically vulnerable populations. To create a repeatable modelling process to identify regional population centers with pandemic vulnerability, readily available COVID-19 and socioeconomic variable datasets were compiled, and linear regression models were built during the early days of the COVID-19 pandemic. The models were validated later in the pandemic timeline using actual COVID-19 mortality rates in states with high population densities, with New York, New Jersey, Connecticut, Massachusetts, Louisiana, Michigan and Pennsylvania showing the strongest predictive results. Our models have been shared with the Department of Health Commissioners of each of these states as input into a much needed “pandemic playbook” for local healthcare agencies in allocating medical testing and treatment resources.

Keywords — Coronavirus; SARS-CoV-2; Pandemic; Socioeconomic status; Predictive model; Healthcare resource allocation

I. INTRODUCTION
Socioeconomic vulnerability can directly influence the severity of pandemics and their impact on mortalities in ways including access to healthcare, residence in crowded housing units and comorbidities. Prior studies of swine flu (H1N1) have pointed to these factors as contributors to the spread and severity of that pandemic. Other studies have identified national level correlations that are helpful, but not actionable at a local level where actual healthcare resource allocation decisions are made.

Early and accurate decisioning for healthcare resource allocations are particularly critical in geographic locations with high population density. This research created a repeatable modelling process that uses readily available data sources to identify the top counties in densely populated states with high likelihoods of disproportionate COVID-19 mortality rates. These models have been shared with the Department of Health Commissioners of New York, New Jersey, Connecticut, Massachusetts, Louisiana, Michigan and Pennsylvania where the models performed best. All Commissioners responded positively which validates our hypothesis that neither other researchers nor the Departments of Health themselves have developed a similar modelling process as a means to allocate scarce healthcare resources such as testing, treatment, education and communication.

II. METHODS
Exploratory data research at a national level was performed using county level data (Federal Information Processing Standards for county
identification; also known as FIPS). COVID-19 mortality datasets (deaths per 100,000 of population) were created using the John’s Hopkins Dataset (https://coronavirus.jhu.edu/map.html) and data from the US Census Bureau. Socioeconomic vulnerability datasets at a county level were created using sub-components of the CDC Social Vulnerability Index (https://svi.cdc.gov/data-and-tools-download.html).

Scatterplots and trendlines were used to identify those variables most correlated with COVID-19 mortalities. Few, if any, social vulnerability variables correlated across all of the 3,142 FIPS counties, but minority status correlated strongly in certain regions, particularly those with high mortality rates.

These findings focused the next steps on state level rather than national level correlations. County-level dependent variable datasets were created using COVID-19 mortality and population data from coronadatascraper.com (data service that scrapes county level COVID-19 data on a daily basis) as well as usafacts.org for cumulative mortalities as of April 8, 2020 and May 8, 2020.

County-level independent variable datasets were created using socioeconomic data from countyhealthrankings.org, a collaboration dataset created by the Robert Wood Johnson Foundation and the University of Wisconsin Population Health Institute. Given the year-to-year stability of most of these socioeconomic variables, the latest data available in the countyhealthrankings.org was used and no attempt was made to augment the dataset to try to match the time-series to either April 8, 2020 or May 8, 2020.

Cumulative COVID-19 specific mortality data (deaths per 100,000 of population) by county for high mortality rate states (NY, NJ, CT, MA, LA, MI, PA) as of May 8th was used as the dependent variable.
The May 8, 2020 date was used to ensure that the dependent variable would be tuned to a timeframe at or around the peak in daily mortalities when healthcare resources (testing, treatment, tracing) are typically most needed. The mortality curves below provide support for May 8th as the overall date for mortality predictions as shown in the Institute of Health Metrics and Evaluation dataset (https://covid19.healthdata.org/).

A stepwise linear regression technique was used to build each state level model. All relevant independent variables (Figure 3) were initially used in the model (i.e., include severe housing problems, but exclude violent deaths). Next, the variable with the lowest T-statistic was removed and the linear regression was re-run. This process was repeated until all T-statistics for the remaining independent variables were near a value of 2 or greater.

III. RESULTS

Predictive models were completed for New York, New Jersey, Connecticut, Massachusetts, Louisiana, Michigan and Pennsylvania with statistically significant results.
Model validation comparing predicted to actual county rankings by cumulative mortality rate (deaths per 100,000 of population) through May 8th and data visualizations using state level maps were completed. These validations were used to share model methods and results with the Commissioners of each state’s Department of Health.

Two further validations were completed as well. The first validation was to check model performance using COVID-19 mortality data on April 8, 2020 instead of May 8, 2020. This validation tested whether models using data available early in the pandemic would have been sufficient to build the models. The same variables were used, but coefficients were recalibrated with the April 8 dataset. April 8 and May 8 model outputs were compared to test for stability in the top counties predicted for high COVID-19 mortality rates. For New York, New Jersey and Connecticut, the models were stable. For Massachusetts, the 4/8 model performance was not strong, but this was easily corrected by using case data in place of mortality data. This is an important finding as it validates the predictive power contained in early case data which is more readily available at the start of a pandemic.
The second validation was to check the independent variables for multi-collinearity, with a specific focus on the correlations between Black and uninsured or socioeconomically vulnerable variables such as severe housing and uninsured. Strong multi-collinearity was seen in Connecticut, Massachusetts, Louisiana and Michigan partially explaining why these variables did not remain in the model after the stepwise regression process.

With models and validations completed, the Departments of Health for New York, New Jersey, Connecticut, Massachusetts, Louisiana, Michigan and Pennsylvania were contacted. Additionally, agents of the New York Department of Health (Northwell Health and CORE) and a third-party statistical modelling firm for Connecticut (COVIDACTNOW) were contacted. Response from these contacts were positive and, in some cases, occurred within an hour of outreach (Northwell Health). This response indicates the strong appetite and need for this type of healthcare resource allocation tool for pandemics and other health crises. In fact, the Pennsylvania Department of Health indicated this tool’s importance in any second waves of COVID-19.

### IV. DISCUSSION

The research described in this manuscript has shown the extent to which Black Americans, people living in crowded housing units, and households with less access to healthcare are at higher risk of severe illness during a pandemic. The results of other studies provide several possible explanations for these results. Lower income households are more likely to live in crowded housing units and multi-family homes. Lower income households are also structurally disadvantaged in their access to medical insurance and healthcare. Some studies have also pointed to a concept called “weathering” within the Black American community. Arline Geronimus, a professor of public health at the University of Michigan, showed through her research that among black communities, coping with financial strain, discrimination and barriers to good education elevates the stress response.
contributing to obesity, diabetes, hypertension and heart disease.\textsuperscript{14}

The CDC conducted research on the co-occurrence of COVID-19 and certain ethnicities using a sample of 580 patients with lab-confirmed data.\textsuperscript{15} Their results showed that more hospitalizations in Black patients than White patients. The researchers cited underlying medical conditions, work circumstance and living conditions to be major factors in COVID-19 mortalities in their sample. For example, members of racial and ethnic minorities are more likely to live in densely populated areas, making it more difficult to practice social distancing and being more susceptible to contracting and spreading COVID-19.\textsuperscript{15} These members also lived farther away from grocery stores and medical facilities, thus being less able to receive necessary resources and medical attention.\textsuperscript{15} Other examples cited included Hispanic and Black American workers employed in higher risk industries and often lacking paid sick leave. The researchers hypothesized that these types of workers were more likely to continue working despite being sick, thus exposing other workers to the disease.\textsuperscript{15} The CDC recommended at the conclusion of this research that public health officials communicate to different population groups about COVID-19 and provide more healthcare services to ethnic minority groups.\textsuperscript{15}

While studies such as these are insightful, we are not aware of any research that translates these impacts into predictive models that can be used locally to direct healthcare resources to the communities most likely to need them, thereby reducing mortalities caused by an ongoing set of institutional inequities.

That said, some organizations have attempted to create healthcare resource allocation methods using descriptive statistics. The Centers for Disease Control and Prevention (CDC) created the social vulnerability index (SVI), allowing the healthcare community to see which factors contribute to socioeconomic vulnerability. The CDC SVI factors are grouped into 4 groups: Socioeconomic status, Household Composition & Disability, Minority Status & Language, and Housing Type & Transportation. Although these factors are crucial inputs in identifying specific vulnerable communities, these four categories of factors alone are not sufficient to create the types of predictive models that state and local healthcare agencies can use. One example of this insufficiency is a recent study at Emory University where researchers identified correlations between COVID-19 mortalities and the SVI at a national level in the US.\textsuperscript{2} While this study is helpful, it stopped short of recommending methods or processes to effectively distribute healthcare resources to specific counties in the US, particularly in the early days of a pandemic.

Another study from the Surgo Foundation states that COVID-19 created new challenges for many communities with a dependence on health and structural factors, which are not completely captured by the CDC SVI.\textsuperscript{16} In addition to the four socioeconomic factors provided by the CDC, the Surgo Foundation added two more factors: Epidemiologic Factors and Healthcare System Factors. Underlying health conditions in addition to healthcare system factors have been proven to greatly enhance a community’s vulnerability during a pandemic. The Surgo Foundation combined these two factors with the CDC SVI to create the COVID-19 Community Vulnerability Index (CCVI). The Surgo Foundation has created heatmaps to show retrospectively which counties were most vulnerable as measured by their CCVI. Similar to the Emory University study however, this methodology did not create a predictive model to identify where the mortalities would be highest at peak periods in a pandemic. We also compared the Surgo Foundation heatmap to our own predictive model rankings and confirmed that our projections of the top counties by per capita mortalities were far closer to reality.
During the early phases of the research described in this manuscript, we used the CDC’s SVI, similar to the Emory University study. We explored all of the sub-category factors in the SVI, but none showed strong correlations at a FIPS county level across the US. We then grouped states together by region and found strong correlations in the most densely populated regions, particularly with the minority status sub-factors. Similar to the Surgo Foundation study, we posited that the CDC’s SVI subfactors alone would be insufficient to build predictive models, so a far more complete independent variable dataset of socioeconomic and healthcare data was sourced from countyhealthrankings.org as discussed earlier. The key differentiation of our work are the predictive models for each state given the local differences in how each of the factors act as predictors of peak COVID-19 per capita mortalities. Our experience in meeting with the Pennsylvania Department of Health in early June 2020 confirms the uniqueness and usefulness of the approach given that they will be using the predictive modelling process for healthcare resource allocations in the event of a potential second wave of COVID-19 in the Fall of 2020. Other state level departments of health were similarly intrigued by our predictive approach including those in New York, New Jersey and Connecticut.

Limitations

The models employed in the analyses are reliant on the accuracy of the datasets compiled. COVID-19 mortality data in particular has been notoriously difficult for states to report accurately at a county level throughout the pandemic for reasons including mortality cause classification errors at local coroner’s offices17.

V. Conclusions

Our modelling process can be used to identify early in future pandemics or health crises, the communities most in need of healthcare resources. The COVID-19 models and the overall methodology have been received with enthusiasm by the New York, New Jersey, Connecticut, Massachusetts, Louisiana, Michigan and Pennsylvania Departments of Health.

ACKNOWLEDGMENT

The author wishes to acknowledge Dr. Fathima Wakeel, Associate Professor at Lehigh University College of Health, for her mentorship throughout this project and for her review of this manuscript. Dr. Wakeel’s guidance was instrumental, particularly in directing the research toward a state level and in driving to actionable recommendations for state departments of health. The author also wishes to acknowledge Iwao Fusillo, Global Head of Data & Analytics for the National Football League (NFL) and Ms. Fusillo’s father, for helping her learn various techniques in dataset creation, statistical analysis and data visualization.

DISCLOSURES

The author has no conflicts of interest to disclose.
