Summary
We report the results of a review of the evidence from studies comparing SARS-CoV-2 culture with reverse transcriptase polymerase chain reaction (rt-PCR), as viral culture represents the best indicator of current infection and infectiousness of the isolate.
We identified fourteen studies succeeding in culturing or observing tissue invasion by SARS-CoV in sputum, naso or oropharyngeal, urine, stool and environmental samples from patients diagnosed with Covid-19.
The data are suggestive of a relation between the time from collection of a specimen to test, copy threshold, and symptom severity, but the quality of the studies was moderate with lack of standardised reporting and lack of testing of PCR against viral culture or Infectivity in animals. This limits our current ability to quantify the relationship between viral load, cycle threshold and viable virus detection and ultimately the usefulness of PCR use for assessing infectiousness of patients.
Prospective routine testing of reference and culture specimens are necessary for each country involved in the pandemic to establish the usefulness and reliability of PCR for Covid-19 and its relation to patients’ factors such as date of onset of symptoms and copy threshold, in order to help predict infectivity.
Introduction

The ability to make decisions on the prevention and management of Covid-19 infections rests on our capacity to identify those who are infected. In the absence of predictive clinical signs or symptoms, the most widely used means of detection is molecular testing using Reverse Transcriptase quantitative Polymerase Chain Reaction (RT-qPCR)\(^2\)\(^3\).

The test amplifies genomic sequences identified in samples. As it is capable of generating results from small samples - it is very sensitive. Amplification of genomic sequence is measured in cycle thresholds (Ct). There appears to be a correlation between Ct values from respiratory samples, symptom onset to test (STT) date and positive viral culture. The lower the Ct value (as a proxy for total viral load) and the shorter the STT, the higher the infectivity potential\(^4\).

Whether probing for sequences or whole genomes\(^5\), in the diagnosis of Covid-19 a positive RT-qPCR cannot tell you whether the person is infectious or when the infection began, nor the provenance of the genetic material. Very early in the outbreak it was recognised that cycle threshold values are a quantitative measure of viral load, but correlation with clinical progress and transmissibility was not yet known\(^6\). A positive result indicates that a person has come into contact with the genomic sequence at some time in the past. However, presence of viral genome on its own is not sufficient proof of infectivity and caution is needed when evaluating the infectivity of specimens simply based on the detection of viral nucleic acids\(^5\). In addition, viral genomic material can be still be present weeks after infectious viral clearance.\(^7\) Like all tests, RT-qPCR requires validation against a gold standard. In this case isolation of a whole virion (as opposed to fragments) and proof that the isolate is capable of replicating its progeny in culture cells is the closest we are going to get to a gold standard.\(^8\)

Our Open Evidence Review of transmission modalities of SARS CoV-2 identified a low number of studies which have attempted viral culture. There are objective difficulties in doing such cultures such as the requirement for a level III laboratory, time and the quality of the specimens as well as financial availability of reagents and culture media to rule out the presence of other pathogens.

As viral culture represents the best indicator of infection and infectiousness, we set out to review the evidence on viral culture compared to PCR, and report the results of those studies attempting viral culture regardless of source (specimen type) of the sample tested.

Methods

We conducted an initial search using LitCovid, medRxiv, Google Scholar and Google for Covid-19 using the terms ‘viral culture’ or ‘viral replication’ and associated synonyms. Search last updated 30\(^{th}\) July 2020.

Results were reviewed for relevance and searches were stopped when no new relevant articles were apparent. For articles that looked particularly relevant citation matching was undertaken and relevant results were identified.

We included studies reporting attempts to culture SARS-CoV-2 and those which also estimated the infectiousness of the isolates. One reviewer extracted data for each study and a second review checked and edited the extraction. We tabulated the data and summarised data narratively by mode of sample: fecal, respiratory, environment or mixed.

Where necessary we wrote to corresponding authors of the included or background papers for additional information. We assessed quality using a modified QUADAS 2 risk of bias tool. We simplified the tool as the included studies were not designed as primary diagnostic accuracy studies.\(^9\)

This review is part of an Open Evidence Review on Transmission Dynamics of COVID-19. Summaries of the included studies and the protocol (v1) are available at: [https://www.cebm.net/evidence-synthesis/transmission-dynamics-of-covid-19/](https://www.cebm.net/evidence-synthesis/transmission-dynamics-of-covid-19/). Searches are updated every 2 weeks.

Results

We identified 114 articles of possible interest and after screening full texts included 14 (see PRISMA\(^10\) flow chart - Figure 1). The salient characteristics of each study are shown in Table 1.

All 14 studies were case series of moderate quality (Table 2. Quality of included studies). We could not identify a protocol for any of the studies. All the included studies had been either published or were available.
Viral cultures for COVID-19 infectivity assessment – a systematic review

In: Analysis of the Transmission Dynamics of COVID-19: An Open Evidence Review

as preprints; all had been made public in 2020. We received four responses from authors regarding clarifying information (see Acknowledgments).

Studies using fecal samples

Five studies used fecal samples which were positive for SARS-CoV-2 based on RT-PCR result\textsuperscript{11-15} and reported achieving viral isolation, and one laboratory study \textsuperscript{16} found that SARS-CoV-2 infected human small intestinal organoids. A further study visually identified virions in colon tissue\textsuperscript{17}.

Studies using respiratory samples

Three studies on respiratory samples report achieving viral isolation. One study assessed 90 nasopharyngeal samples and cultured 26 of the samples, and positive cultures were only observed up to day eight post symptom onset; \textsuperscript{4} another study obtained 31 cultures from 46 nasopharyngeal and oropharyngeal samples; \textsuperscript{18} while 183 nasopharyngeal and sputum samples produced 124 cases in which a cytopathic effect was observed although the denominator of samples taken was unclear \textsuperscript{19}.

Studies using environmental samples

Two possible positive cultures were obtained from 95 environmental samples in one study that assessed the aerosol and surface transmission potential of SARS-CoV-2 \textsuperscript{20}.

Mixed sources

Five studies reported viral culture from mixed sources. Using 60 samples from 50 cases of Covid-19, viral culture was achieved from 12 oropharyngeal, nine nasopharyngeal and two sputum samples\textsuperscript{5}. Jeong et al \textsuperscript{11} who reported isolation live virus from a stool sample also reported that from of an unreported number of nasopharyngeal, oropharyngeal, saliva, sputum and stool samples, one viral culture was achieved: ferrets inoculated with these samples became infected; SARS-CoV-2 was isolated from the nasal washes of the two urine-treated ferrets and one stool-treated ferret\textsuperscript{11}. An unreported number of samples from saliva, nasal swabs, urine, blood and stool collected from nine Covid-19 patients produced positive cultures and a possible specimen stool culture\textsuperscript{21}. One study showed that from nine nasopharyngeal, oropharyngeal, stool, serum and urine samples, all nine were culturable, including two from non-hospitalised Covid-19 patients\textsuperscript{22}. Yao and colleagues cultured viable viral isolates from seven sputum samples, three stool samples and one nasopharyngeal sample of 11 patient aged 4 months to 71 years, indicating that the SARS-CoV-2 is capable of replicating in stool samples as well as sputum and the nasopharynx. \textsuperscript{23} All samples had been taken within 5 days of symptom onset. The authors also report a relationship between viral load (copy thresholds) and cytopathic effect observed in infected culture cells \textsuperscript{24}.

The relationship between RT-PCR results and viral culture of SARS-CoV-2

It is not possible due to the reporting within the studies to currently make a quantitative assessment of the association between RT-PCR results and the success rate of viral culture within these studies. These studies were not adequately sized nor performed in a sufficiently standardised manner and may be subject to reporting bias.

Discussion

This review shows that a number of studies have attempted and successfully achieved culture of SARS-CoV-2 in the laboratory, using a range of respiratory, fecal or environmentally collected samples. The rate of success is difficult to assess from available studies, and additional studies that we are unaware of may have been performed with no viral culture achieved. There may be a positive relationship between lower cycle count threshold and viral culturability, but more studies with standardised methods are needed to establish the magnitude and reliability of this association.

The purpose of viral testing is to assess the relation of the micro-organism and hazard to humans, i.e. its clinical impact on the individual providing the sample for primary care and the of risk of transmission to others for public health. PCR on its own is unable to provide such answers. When interpreting the results of
Viral cultures for COVID-19 infectivity assessment – a systematic review

In: Analysis of the Transmission Dynamics of COVID-19: An Open Evidence Review

rt-PCR it is important to take into consideration the clinical picture, the cycle threshold value and the number of days from symptom onset to test (STT)\(^25\). Several of our included studies assessed the relationship of these variables and there appears to be a time window during which shedding is at its highest with low copy threshold and higher possibility of culturing a live virus. We propose that further work should be done on this with the aim of constructing a calibrating algorithm for PCR which are likely to detect infectious patients. PCR should be continuously calibrated against a reference culture in Vero cells in which cytopathic effect has been observed\(^4\). Confirmation of visual identification using methods such as an immunofluorescence assay may also be relevant for some virus types\(^8\).

We are unsure whether SARS CoV-2 methods of cell culture have been standardised. Systems can vary depending upon the selection of the cell lines; the collection, transport, and handling of and the maintenance of viable and healthy inoculated cells\(^26\). We therefore recommend that standard methods for culture should be urgently developed. If identification of viral infectivity relies on visual inspection of cytopathogenic effect, then a reference culture of cells must also be developed to test recognition against infected cells. Viral culture may not be appropriate for routine daily results, but specialized laboratories should rely on their own ability to use viruses as controls, perform complete investigations when needed, and store representative clinical strains whenever possible\(^26\). In the absence of a culture, ferret inoculation of specimen washings and antibody titres could also be used. It may be impossible to produce a universal Cycle threshold value as this may change with circumstances (e.g. hospital, community, cluster and symptom level) and the current evidence base is thin.

We suggest the WHO produce a protocol to standardise the use and interpretation of PCR and routine use of culture or animal model to continuously calibrate PCR testing, coordinated by designated Biosafety Level III laboratory facilities with inward directional airflow\(^27\).

The results of our review are similar to those of the living review by Cevick and colleagues\(^28\). Although the inclusion criteria are narrower than ours, the authors reviewed 79 studies on the dynamics, load and shedding for SARS CoV-1, MERS and SARS CoV-2 from symptoms onset. They conclude that although SARS-CoV-2 RNA shedding in respiratory (up to 83 days) and stool (35 days) can be prolonged, duration of viable virus is relatively short-lived (up to a maximum of 8 days from symptoms onset). Results that are consistent with Bullard et al who found no growth in samples with a cycle threshold greater than 24 or when symptom onset was greater than 8 days. Thus, blanket detection of viral RNA cannot be used to infer infectiousness. Length of excretion is also linked to age, male gender and use of steroids and possible severity of illness. Of note, live virus excretion peaked later in SARS CoV-1 and MERS\(^28\).

The limits of our review are the low number of studies of relatively poor quality with lack of standardised reporting and lack of gold testing for each country involved in the pandemic. This limits our ability to quantify the relationship between viral load, cycle threshold and viable virus detection. We plan to keep updating this review with emerging evidence.

**Conclusion**

The current data are suggestive of a relation between the time from collection of a specimen to test, copy threshold, and symptom severity, but the quality of the studies limits firm conclusions to be drawn. We recommend that a uniform international standard for reporting of comparative SARS-CoV-2 culture with index test studies be produced. Particular attention should be paid to the relationship between the results of testing, clinical conditions and the characteristics of the source patients, description of flow of specimens and testing methods. Defining cut off levels predictive of infectivity should be feasible and necessary for diagnosing viral respiratory infections using molecular tests\(^29\).

<td>From 1049 samples, 611 SARS-CoV-2 isolates were cultured. 183 samples testing positive by RT-PCR (9 sputum samples and 174 nasopharyngeal swabs) from 155 patients, were inoculated in cell cultures. SARS-CoV-2, RNA rRT-PCR targeted the E gene. Nasopharyngeal swab fluid or sputum sample were filtered and then inoculated in Vero E6 Cells. All samples were inoculated between 4 and 10 h after sampling and kept at + 4 °C before processing. After centrifugation they were incubated at 37 °C. They were observed daily for evidence of cytopathogenic effect. Two subcultures were performed weekly and scanned by electron microscope and then confirmed by specific RT-PCR targeting E gene. Of the 183 samples inoculated in the studied period of time, 129 led to virus isolation. Of these 124 samples had detectable cytopathic effect between 24 and 96 h. There was a significant relationship between Ct value and culture positivity rate: samples with Ct values of 13–17 all had positive culture. Culture positivity rate decreased progressively according to Ct values to 12% at 33 Ct. No culture was obtained from samples with Ct &gt; 34. The 5 additional isolates obtained after blind subcultures had Ct between 27 and 34, thus consistent with low viable virus load.</td>

A laboratory-confirmed COVID-19 severe pneumonia case, who experienced onset on January 16, 2020 and was sampled on February 1, 2020. The interval between sampling and onset was 15 days. The full-length genome sequence indicated that the virus had high nucleotide similarity (99.98%) to that of the first isolated novel coronavirus isolated from Wuhan, China.

Vero cells, viral particles with typical morphology of a coronavirus could be observed under the electron microscope. Viral receptors ACE2 and viral nucleocapsid staining were performed.

1 plus an unknown additional number of fecal samples from RNA-positive patients. [not reported]

Histological staining (H&E) as well as viral receptor ACE2 and viral nucleocapsid staining were performed. Positive staining of viral nucleocapsid protein was visualized in the cytoplasm of gastric, duodenal, and rectal glandular epithelial cell, but not in esophageal epithelium of the 1 patient providing these tissues. Additionally, positive staining of ACE2 and SARS-CoV-2 was also observed in gastrointestinal epithelium from other patients who tested positive for SARS-CoV-2 RNA in feces. Results not reported.
Viral cultures for COVID-19 infectivity assessment – a systematic review
In: Analysis of the Transmission Dynamics of COVID-19: An Open Evidence Review

The samples of the 11 patients involved in this study were collected during the early phase of the COVID-19 break out in China, dates ranging from 2nd of January to the 2nd of April 2020.

All except one of the patients had moderate or worse symptoms. Three patients had co-morbidities and one patient needed ICU treatment. Seven patients had sputum samples, one nasopharyngeal and three had stool samples.

The samples were pre-processed by mixing with appropriate volume of MEM medium with 2% FBS, Amphotericin B, Penicillin G, Streptomycin, and TPCK-trypsin. The supernatant was collected after centrifugation at 3000 rpm at room temperature. Before infecting Vero-E6 cells, all collected supernatant was filtered using a 0.45 µm filter to remove cell debris etc.

Vero-E6 cells were infected with 11 viral isolates and quantitatively assessed their viral load at 1, 2, 4, 8, 24, and 48 hours post-infection (PI) and their viral cytopathic effects (CPE) at 48 and 72 hours PI. and examined whether the viral isolates could successfully bind to Vero-E6 243 cells as expected. Super-deep sequencing of the 11 viral isolates on the Novaseq 6000 platform was performed.
