Highlights

- The first study identified significant relationships between green spaces and the racial disparity of SARS-CoV-2 infection rates.
- A nationwide study of 135 most urbanized counties of the United States.
- The black-white racial disparity of SARS-CoV-2 infection rates was measured within each county.
- A higher ratio of green spaces is associated with a lower racial disparity of SARS-CoV-2 infection rates.
- Four green space factors are positively associated with a lower racial disparity of SARS-CoV-2 infection rates.
Abstract

There is striking racial disparity in the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection rates in the United States. We hypothesize that the disparity is significantly smaller in areas with a higher ratio of green spaces at the county level, because green spaces provide health benefits to people of different races through multiple pathways. We suggest that they are an equalizing salutogenic factor, modifying infection exposure. This study used the 135 most urbanized counties across the United States as sample sites. County level data on the SARS-CoV-2 infection rates of blacks and whites in each county were collected. The ratio of green spaces by land-cover type at the county level was calculated from satellite imagery. An ecological hierarchical regression analysis measured cross-sectional associations between racial disparity in infection rates and green spaces, after controlling for confounding factors. We found significantly higher infection rate among black individuals compared to white individuals. More importantly, a higher ratio of green spaces at the county level is significantly associated with a lower racial disparity in the SARS-CoV-2 infection rate. Further, we identified four green space factors that have significant negative associations with the racial disparity in SARS-CoV-2 infection rates, including open space in developed areas, forest, shrub and scrub, and grassland and herbaceous.

Keywords: racial disparity; health disparity; SARS-CoV-2; COVID-19; green spaces; pathway
Introduction

Racial disparity in health is a significant problem in many countries and can lead to social conflicts, economic crises, and loss of life\(^1\),\(^2\). The black–white health disparity in the United States is a representative example in developed economies and is unsurprisingly manifest in the ongoing coronavirus disease 2019 (COVID-19) pandemic\(^3\),\(^4\),\(^5\),\(^6\). COVID-19 results from infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and the SARS-CoV-2 infection rate in black individuals is significantly higher, proportionally, than that in white individuals\(^4\),\(^7\),\(^8\).

Although studies of the COVID-19 pandemic are quickly accumulating, only a small portion have examined racial disparity in infection rates\(^9\),\(^10\),\(^11\),\(^12\). Most of these studies focused on relationships between socioeconomic, demographic, or pre-existing chronic disease factors and racial disparity in SARS-CoV-2 infection rates\(^4\),\(^13\),\(^14\). None of the studies have directly examined effects of urban environmental factors. Evidence suggests that green spaces may have positive and independent effects on reducing the racial disparity in various long-term health outcomes\(^15\),\(^16\),\(^17\),\(^18\),\(^19\),\(^20\),\(^21\). Yet, to our knowledge, there is no evidence to support green space’s effect on reducing racial disparity in SARS-CoV-2 infection rates. This lack of knowledge may mean missing opportunities to slow down the COVID-19 pandemic, and to moderate future epidemics by through urban greening. Our nationwide study is an initial ecological cross-sectional study aiming to establish a county-level relationship between black–white racial disparity in SARS-CoV-2 infection rates and the amount and type of green spaces in the United States.

**A new trend: Significant environmental effects on racial disparity in health**

Many studies have explored potential mechanisms that maintain and exacerbate general racial disparity in health outcomes to identify effective policies to address such inequities. Much of the racial disparity seems to be influenced by differences in socioeconomic and demographic factors\(^3\),\(^4\),\(^14\). Still, disparities remain significant after controlling for these factors. For example, the life expectancies of higher socioeconomic status (SES) blacks and whites are 7.1 and 6.8 years longer, respectively, than those of their lower SES counterparts\(^22\),\(^23\). Life expectancy of blacks is at least three years less than that of whites with a comparable income level, at every level of income\(^23\).

Racial disparity is also pronounced in birth outcomes; for example, the infant mortality rate for college-educated black women is 2.5 times higher than that for college-educated white women\(^23\).
These studies suggest that persistent racial health disparities are due, in part, to other types of systemic disparities between races.

After controlling for SES factors, an under-studied reason for racial disparity in health outcomes is built environment disparity. People of different races, especially blacks and whites in the USA, have lived in neighborhoods with distinct environmental qualities. Neighborhoods that are the long-term home of more black people have, on average, fewer green spaces for physical activity, lower accessibility to healthy food, and lower traffic or crime-related safety. These findings have prompted studies in new directions. Researchers across disciplines have shifted from investigating exclusively social, economic, and educational interventions, and are now also investigating physical environmental interventions as a means to alleviate persistent racial-disparities.

**Positive effects of green spaces on human health**

The significantly positive effects that green spaces have on human health have drawn considerable attention from researchers, public health professionals, and governmental officers over the past decades. A growing number of studies have measured these effects at the regional, municipal, neighborhood, and property-site levels. Consensus has emerged that green spaces can influence human health through five major pathways, namely attention restoration, stress reduction, enhanced social cohesion and social capital, increased physical activity, and supply of ecological products and services. These pathways have been demonstrated across different geographic, social, and cultural contexts.

**Green spaces reduce racial disparity in health: Circumstantial evidence and knowledge gaps**

One line of research might be highly relevant to racial disparity in SARS-CoV-2 infection rates: green spaces can mitigate health disparities among populations with distinctively different SESs. A series of ground-breaking observational and survey studies conducted by Kuo and Sullivan (2001), Sullivan et al. (2004), and Taylor et al. (2002) found that a greater amount of green space in public housing communities was significantly correlated with a higher level of self-discipline, a lower level of mental fatigue, a higher level of social activity and cohesion, and a lower level of stress and aggressive behavior in residents. Mitchell and Popham (2008) published a nationwide survey-based study revealing that the association between income level
and all-cause mortality and circulatory disease mortality at the neighborhood level can be moderated by the amount of green space in a neighborhood. The study suggested that more exposure to green space can reduce the health disparity caused by income disparity. Lovasi et al. (2009)\textsuperscript{21} found that the supply of public green spaces can reduce health disadvantages due to obesity and obesity-related illnesses in residents of low SES, by encouraging physical exercise. Branas et al. (2011, 2018)\textsuperscript{56, 57} conducted citywide experimental studies, and found that the supply of green open space in low-income neighborhoods can significantly reduce crime, violence, stress, and fear, and increase daily exercise in those neighborhoods.

Many of these studies have examined the relationships between the supply of green spaces and health disparities in long-term health between populations withdistinctively different SESs\textsuperscript{58, 59}. While SES disparity is relevant to racial disparity, it is not fully representative of it\textsuperscript{60}. Furthermore, the potential for exposure to green spaces to attenuate racial disparity in the risk of infection by airborne viruses, such as SARS-CoV-2, has not been investigated. This is a critical knowledge gap that may limit our opportunities to moderate the current pandemic and epidemics in the future.

**Hypothesis**

We hypothesized that the black–white racial disparity in the USA’s SARS-CoV-2 infection rates is significantly less in urbanized counties with a higher ratio of various types of green spaces.

**Methods**

**Study design**

We compared the black–white disparity in SARS-CoV-2 infection rates in populations living in urbanized counties of the United States that have different amounts of green spaces, while adjusting for potential confounding factors of these counties. The infection data were retrieved on July 10, 2020. We adopted a within-subject (within-county) research design with a representative sample across the country. Black–white disparity was measured as the difference in the infection rate of blacks and whites in the same county. This allowed us to largely remove the bias caused by between-subject (between-county) factors that may lead to the uneven spread of SARS-CoV-2 in different counties, such as the distance to COVID-19 epicenters, climate, or local government policies. The study is cross-sectional in the sense that it does not analyze across time and ecological in the sense that it uses data aggregated at spatial unit of analysis (county).
Study areas

The United States is among the countries most severely impacted by COVID-19. It also has severe black–white racial inequalities in SARS-CoV-2 infection rates. Our study used counties as the basic unit of analysis, which are the fundamental administrative unit in the United States. There are a total of 3,142 counties or county-equivalent areas in the United States.

The most urbanized counties were chosen because we assumed that the racial inequality in the SARS-CoV-2 infection rates is more pronounced in denser urban environments. First, we identified a list of 314 large cities with a population ≥ 100,000 in 2019. Second, we identified a total of 229 counties containing or overlapping these large cities. Third, counties without infection data for blacks and whites were excluded. A total of 135 counties were chosen as our study areas. The total population in these counties was 132,350,027, which comprised 40.3% of the total population in the United States. We chose counties rather cities as the unit of analysis because the infection data for blacks and whites were often unavailable at the city level.

SARS-CoV-2 infection rates

The infection data were collected from the county health department portals on July 10, 2020. Only SARS-CoV-2 infections in whites and blacks were collected in this study. We calculated the SARS-CoV-2 infection rates for whites and blacks (numbers of cases per 100k) based on the total white and black populations in each county, respectively, which were retrieved from the 2019 census data\textsuperscript{61}. The racial disparity in the SARS-CoV-2 infection rates was calculated as the difference between the infection rate in blacks and the infection rate in whites in the same county.

Green spaces

We used three datasets to assess green spaces, namely the National Land Cover Datasets in 2016 (NLCD 2016), the Tree Canopy Cover Datasets of the United States Forest Service (USFS), and NDVI.

The NLCD 2016 provides spatially explicit and reliable information on the national land-cover classification based on Landsat imagery at 30-meter resolution\textsuperscript{62}. The overall agreement ranges from 71% to 97% between different land-cover classifications and reference data\textsuperscript{62}. The NLCD 2016 has 16 types of land covers. We considered the following land-cover types with dominant natural elements: developed open space, deciduous forest, evergreen forest, mixed forest, shrub...
and scrub, grassland and herbaceous, pasture and hay, cultivated crops, woody wetlands, and emergent herbaceous wetlands (Appendix Table 2). Deciduous/evergreen/mixed forest were combined into a new land-cover denoted “forest”. The ratio of these green spaces over the total county area in each county was calculated.

The Tree Canopy Cover Dataset was derived from the NLCD by the USFS. It provides estimates of the percent tree canopy cover at 30-meter resolution. We aggregated the total tree-canopy cover estimates for each county and then divided it by the county area.

The NDVI is a widely used index that measures the quantity of green vegetation cover at the pixel level via remote sensing. We obtained the NDVI at a 30-meter resolution from the Google Earth Engine, which integrates Landsat 8 imagery in its cloud platform. Four pixel-level average values were calculated for each county in each month from March to July in 2020, and we finally obtained the mean of four monthly NDVI values as a proxy for overall green spaces coverage during the research period.

However, we found that the land-cover dataset had high multicollinearity with two other measurements of green spaces. For instance, the NDVI and forest land-cover are strongly correlated (Pearson correlation coefficient: $r = 0.64, p < 0.001$), as are tree canopy and forest ($r = 0.85, p < 0.001$). Therefore, we only used measures from the land-cover dataset.

**Confounding factors**

Previous studies have shown that demographic and socioeconomic characteristics are important predictors of SARS-CoV-2 infection risk or racial disparity in this risk. From the 2019 census data, we obtained the population density, the female population ratio, the difference in black–white population, the difference in black–white older adults, household size, housing value, the rate of high school graduates or higher, the rate of households with broadband, median household income, the poverty rate, healthcare receipts data, travel time to work, the employment rate, and the number of firms for our study areas (Appendix Table 1).

Pre-existing chronic disease is another indispensable dimension that might be connected with the racial disparity in SARS-CoV-2 infection rates. Thus, county-level pre-existing chronic disease factors were collected from the 2016–2018 interactive heart disease and stroke data collated by the Centers for Disease Control and Prevention. The pre-existing chronic disease
factors that we used were the coronary heart disease death rate, the heart failure death rate, the diagnosed diabetes rate, and the obesity rate for each county (Appendix Table 1).

All confounding factors were represented by proportional variables (e.g., per 100 k, density, ratio, and median value) or the difference between blacks and whites at the county level. Therefore, they were consistent with the dependent variable.

**Statistical analysis**

Three statistical analysis steps were performed. First, a paired $t$-test was used to examine whether there was a significant difference between SARS-CoV-2 infection rates in blacks and whites in the same county. Second, a variance inflation factor (VIF) test was used to remove potential multicollinearity among the independent variables. We adopted the threshold value of VIF = 4\textsuperscript{67}. All of the factors with a VIF ≥ 4 were excluded from our models (Appendix Tables 1 & 2).

Third, hierarchical linear-regression models were used to examine the associations between the black–white difference in the SARS-CoV-2 infection rates and green space factors, while controlling for other confounding factors. The first model (Model 1) included the socioeconomic and demographic factors only. The second model (Model 2) additionally included pre-existing chronic disease factors. The last model (Model 3) additionally included green space factors, on the basis of Model 2.

All of the analyses were performed using R v4.0.2\textsuperscript{68}. The model $R^2$ values, adjusted $R^2$ values, standardized coefficient ($\beta$) values, 95% confidence intervals, and $p$-values were reported.

**Results**

Results are presented in three sections. First, we present the incidence of SARS-CoV-2 infections in the sample of 135 most urbanized counties in the United States and examine the extent to which there are differences in infection rates among black and white populations. Second, we report demographic and green space characteristics of the sampled counties. Third, we employ hierarchical linear modeling to examine the extent to which, after controlling for confounding factors, the ratio of green spaces are associated with black-white disparities in SARS-CoV-2 infection rates. Finally, we report four green space factors that have significant negative associations with the racial disparity in SARS-CoV-2 infection rates.
Does a racial disparity in infection rates exist?

As of July 10, 2020, there were a total of 1,425,461 cases of SARS-CoV-2 infection in the 135 most urbanized counties in the United States, which accounted for 47% of the total cases of infection (3,038,325) in the United States (Figure 1). The 135 most urbanized counties were selected because they contain or overlap with 314 large cities with a population ≥ 100,000 in 2019 (see details in Methods). The county-level average infection rate for whites was 497 persons per 100,000 population, whereas the infection rate for blacks was approximately twice this (988 persons per 100,000 population) (Figure 1 & Table 1). The average black–white difference in the infection rate was 447 persons per 100,000 population. Whites had a higher infection rate than blacks in only 11 out of the 135 counties (Figure 2). As expected, a paired t-test revealed that the difference in infection rates between blacks and whites is significant, with t (134) = 12.757 and p < 0.001 (Figure 3).

Figure 1. SARS-CoV-2 infection rates of blacks and whites in the 135 most urbanized counties of the United States. Pink column indicates infection rate for blacks; blue column indicates infection rate for whites. The height of columns indicates the magnitude of infection rate.
Figure 2. Racial disparity in the SARS-CoV-2 infection rates between blacks and whites in the 135 most urbanized counties of the United States. Cyan column indicates black infection rate is higher than white; purple column indicates white infection rate is higher than black. The height of columns indicates the magnitude of disparity.

Figure 3. The mean SARS-CoV-2 infection rate of blacks is approximately twice that of whites (988 vs. 497 per 100,000 population). Significant at $p < 0.001$ using a paired t-test. The error bar represents standard deviation.
**Characteristics of the sampled counties**

Table 1 shows that there are proportionally more whites than blacks in the study areas, which is consistent with the overall racial composition in the United States. The sample includes an average of 2.6 persons per household and a notably large range in median household income across counties. In terms of the green space factors, the sample includes a high quantity of developed open space and forest cover (Figure 4), and low levels of shrub and scrub, and grassland and herbaceous cover. Figure 4 shows the ratio of four types of green space in each county.

Table 1. Descriptive statistics for SARS-CoV-2 infection rates, socioeconomic and demographic factors, pre-existing chronic disease factors, and green space factors in the USA’s 135 most urbanized counties.

Modeling association of green spaces and infection disparity

By fitting three hierarchical regression models, we identify three relevant associations (Table 2). Model 1 shows that socioeconomic and demographic factors have a significant association with racial disparity in the SARS-CoV-2 infection rate across the USA’s 135 most urbanized counties (adjusted $R^2$ of 0.12, $p = 0.003$). We also note that there is a significantly negative association between household size and racial disparity in SARS-CoV-2 infection rates, such that as average household size increases, infection disparity falls.

After adding pre-existing chronic disease factors into Model 2, the explanatory power of Model 2 slightly decreases (adjusted $R^2 = 0.11$, $p = 0.007$). Model 2 shows that the combination of socioeconomic, demographic, and pre-existing chronic disease factors is associated with racial disparity. However, the overall statistical significance of Model 2 was not substantially better than that of Model 1 ($p = 0.430$ for the sum-of-squares difference).
After adding green space factors into Model 3, the overall explanatory power of Model 3 increased by 18% (adjusted $R^2 = 0.29, p < 0.001$). Model 3 reveals that four green space factors are independently negatively associated with racial disparity. These are: land-cover ratio of developed open space; forest; shrub and scrub; and grassland and herbaceous. In addition, household size is negatively associated with SARS-CoV-2 infection rate disparity between races, while death from heart failure rate is positively associated with it.

To improve our understanding of the associations between the four green spaces and racial disparity in SARS-CoV-2 infection rates, we plotted the independent effects of the four green spaces (using the effects package of the statistical software R$^6^9$). Figure 5 clearly demonstrates...
the negative relationships between the proportion of the four types of green space in counties and the racial disparity in SARS-CoV-2 infection rates.

![Graphs](image)

**Figure 5.** Individual effects of the ratio of four green spaces on the black–white racial disparity in SARS-CoV-2 infection rates (in Model 3, with non-greenspace predictors fixed). a developed open space. b forest. c shrub and scrub. d grassland and herbaceous. Shaded areas represent the pointwise 95% confidence interval. Points represent partial residuals. Straight line represents the linear fitting of the effects. Dashed line represents the progressive fitting of the effects.

**Discussion**

Significant associations between socioeconomic, demographic, and pre-existing chronic disease factors and the racial disparity in SARS-CoV-2 infection rates have been reported by a number of ecological studies. Some urban environmental factors, such as overcrowding housing conditions, living in senior living communities, living in high-density urban areas, and a long commute distance, are associated with a greater racial disparity in SARS-CoV-2 infection rates.
However, no study examined the relationship between green spaces and racial disparity in SARS-CoV-2 infection rates.

In this study of the 135 urbanized counties in the United States, we found a large and statistically significant disparity in infection rates of the SARS-CoV-2 virus for black and white populations. Using hierarchical linear modelling, we found that the combination of socioeconomic, demographic, and pre-existing chronic disease conditions explained around 11% of variance in racial disparity. Adding green spaces explained an additional 18% of variance. Specifically, we identified four types of green space factors that are significantly associated with the racial disparity in SARS-CoV-2 infection: open space in developed areas, forest, shrub and scrub, and grassland and herbaceous.

In the paragraphs that follow, we consider possible mechanisms through which greater amounts of green spaces within a county might contribute to a reduction in racial disparity in SARS-CoV-2 infection rates. The plausible mechanisms are supported by theoretical and empirical evidence. We elaborate the contributions of our findings and identify questions for future research. We think that our study is the first to find that green space factors have significant independent effects on the racial disparity in COVID-19 infection rates, albeit using an ecological study design.

**Interpretation of key findings**

Variations in county-level open space in developed areas, forest, shrub and scrub, and grassland and herbaceous were all significantly negatively correlated with the size of discrepancy in black-white infection rates. In urban counties with more green spaces available, the racial disparity in SARS-CoV-2 infection rates was lower.

We propose that four mechanisms may account for this pattern. Green spaces deliver the following benefits: facilitate physical activity\(^{33, 51, 53}\); promote mental and social health\(^{47,48}\); encourage social activities at a safe physical distance\(^75\); and improve air quality at the neighborhood and city levels\(^76\). All of these may have an influence on reducing racial disparities in infection rates.

First, areas with a large portion of green spaces provided free access to residents of all racial population and promoted physical activity before and during the pandemic\(^77, 78\). This may have enhanced residents’ immune system regardless of race and moderated factors behind race-based infection disparities\(^79, 80, 81\). Physical activity conducted in nature provides additional benefits
compared with physical activity conducted in indoor environment\textsuperscript{82, 83, 84}. As we know, black people tend to living in communities with fewer green spaces for physical activity\textsuperscript{27, 28, 29, 30}. Therefore, black people who can access open green spaces may accrue health benefits from conducting physical activity in these green spaces, and therefore potentially have lower infection rate than black people who cannot access open green spaces.

Second, the presence of more green spaces may have enhanced mental and social health regardless race before and during the pandemic\textsuperscript{55}, providing multiple benefits that moderate risks that otherwise fall more heavily on black communities. It is feasible that disadvantaged groups and races may have heavier stress burdens, especially during the pandemic\textsuperscript{18, 19, 20, 21}. Visual or physical contact with urban green spaces can reduce mental fatigue\textsuperscript{53, 85}, reduce mental stress\textsuperscript{35, 86, 87, 88}, and enhance self-discipline\textsuperscript{52} at the individual level, which can promote immune system function and self-control behaviors in daily life. It can also reduce negative moods\textsuperscript{89, 90} and verbal and behavioral aggressiveness\textsuperscript{50}, which can enhance trust\textsuperscript{54, 91}, collaboration\textsuperscript{92}. This could promote a stronger collective stewardship of the living environment and previous studies found a stronger environmental stewardship can reduce environment-health disparities\textsuperscript{16, 93}.

Third, more green spaces can decrease the SARS-CoV-2 infection risk by improving air quality and decreasing exposure to air pollutants (e.g., PM\textsubscript{2.5}) that are associated with higher SARS-CoV-2 infection rates\textsuperscript{94, 95}. Black households tend to live in higher density, more polluted streets, compared with white households\textsuperscript{27, 28, 29, 30}. The supply of green spaces would be of greater relative benefits to black populations than white populations. Studies have reported that air quality in high-density residential areas in inner cities is significantly worse than that in suburban and rural residential areas\textsuperscript{96}. A greater supply of green spaces, especially in urban areas, may reduce this significant environmental disparity\textsuperscript{17, 19}, thereby contributing to a lower racial disparity in SARS-CoV-2 infection rates. We note, however, that relying on urban green spaces is not sufficient to create healthy air environments\textsuperscript{97} for the whole urban area thus provision of large-scale green spaces beyond the urban area is critical to achieving this goal\textsuperscript{76}.

Fourth, more green spaces can lower the risk of infection by providing all racial populations with ample areas for social activities, while allowing safe physical distance to be maintained\textsuperscript{75}. Staying with the idea of unequal effects of green space increments, for economic and social reasons, black households in the USA have lower average levels of ownership of private open green space than whites, and live in more crowded neighborhoods\textsuperscript{25}. Black populations are more likely than
white populations in the USA to socialize in crowded indoor spaces. Therefore, black people with access to open green spaces are more likely to socialize in outdoor spaces, than black people without access to such green spaces.

In sum, greater amounts of green spaces will have a stronger health effect on black households compared to white. This, we suggest, is a crucial mechanism explaining our regression findings. Other things being equal, a rise in the quantity or accessibility of green spaces in an area might be expected to have an equal effect on black and white. However, black households are less likely to access green spaces than white households. The marginal health (and other) benefits to black households resulting from more green spaces, will be greater than for whites.

Contributions and implications

This study makes three theoretical and practical contributions, which will influence future research, policymaking, and design practice.

First, to the best of our knowledge, this study is the first to measure whether and to what extent green spaces within and beyond developed urban areas are associated with racial disparities in rates of contagious disease infection. Although a few studies have identified some built environment factors, such as crowded living conditions, staying in senior living communities, and dense urban areas, are related to racial disparity in SARS-CoV-2 infection rates, none have addressed green spaces.

Second, we adopted a within-subject research design with a standard spatial sampling unit across the country, giving a representative study for USA urban counties. In contrast with previous studies on COVID-19 that examined associations between SARS-CoV-2 infection rate or COVID-19 mortality rate across counties or cities, our study focused on comparing difference in SARS-CoV-2 infection rates among whites and blacks in the same county. By comparing racial disparity in infection rates within each county we obtain greater statistical validity, as this approach mitigates bias caused by uneven spread of infections across counties due to differences in national road network accessibility, airports and railway connectivity, governmental regulations, social norms, and quantity and quality of healthcare services.

Third, our study suggests that green space as a type of urban infrastructure should be considered to be relevant interventions to reduce the racial disparity of infectious diseases with characteristics similar to the current pandemic. Providing an adequate supply of accessible and
well-designed green spaces in urban areas, and preserving and developing natural green spaces across county areas, is part of an epidemic and pandemic-resilience strategy for highly urbanized areas. Considering that urban and agricultural areas are rapidly encroaching on forest, grassland, and many other natural landscapes inside and/or outside cities worldwide\textsuperscript{103, 104}, it is crucial to maintain and increase efforts to preserve scarce urban green spaces. As well as achieving environmental goals, we show that this approach can also be expected to help deliver health and racial equality agenda.

\textbf{Limitations and opportunities for future research}

This study has some limitations, that point to opportunities for future research.

We collected SARS-CoV-2 infection data from the governmental website of each county in the United States. The quality of data is credible for each county, but the methods of collecting and sorting data may have varied across counties. Moreover, there are a total 229 counties containing or overlapping all cities with a population $\geq$ 100,000 in the United States. However, infection data were unavailable for 94 counties, leaving a set of high-quality data from 135 counties.

This study only examined the problem in the US at the county level. Although the racial disparity in SARS-CoV-2 infection rates in the United States might be a good example for countries with diverse racial population\textsuperscript{6, 9, 105}, we suggest that this research should be duplicated in other countries, to fully determine the complex issue of generally disadvantaged sub-groups in relation to environmental exposure and pandemic dynamics.

This study provides a base-line analysis of green spaces and racial disparity in pandemic infections. It is limited by the normal constraints of a cross-sectional design and of an ecological design. Cross-sectional associations do not imply causality and we cannot avoid the possibility of ecological fallacy. There are possibilities that can be investigated in further studies. Nevertheless, findings of this study echo findings of many published studies that reported causal links between more green spaces and better health status and lower health disparities.

Lastly, a caveat can be raised with respect to possible ecological bias: The access to data in SARS-CoV-2 infection rates at the neighborhood scale was not available, which made us cannot analyze the distribution of green spaces for races at the neighborhood scale. It is possible an unequal allocation of green spaces could lead to races’ unequal exposures to green spaces, which need to be further examined in a future study at a finer spatial scale. Two arguments remain
reasonable albeit the possibility of that bias: More green spaces lead to greater marginal health benefits to black households and then a smaller racial disparity in SARS-CoV-2 infection rates; Large patches of natural green spaces outside the city, such as forest and natural grassland and herbaceous, can create adjusting environmental quality for the whole urban area thus can reduce racial disparity in SARS-CoV-2 infection rates. Nevertheless, we call future studies should further examine the problem and proposed arguments.

**Conclusion**

This study is an initial effort to understand the relationships between environmental factors and racial disparity in SARS-CoV-2 infection rates. We employed hierarchical regression analysis to perform within-county comparisons of the infection rates of the two major racial groups. After controlling for potential confounding factors, we found that four green space factors have independent statistical power to interpret the racial disparity. The findings suggest that the supply of open green space in developed urban areas and natural green spaces across a county may help to reduce racial disparity in SARS-CoV-2 infection rates. The findings in this study tentatively support the potential for exposure to green spaces to attenuate racial disparity.58
