Abstract

Aim
The aim of this study was to estimate the prevalence and causes of vision impairment (VI) in the Norwest of Portugal.

Methods
Information about people with VI was obtained from different sources in the Norwest of Portugal during a period spanning years 2014-2015. Log-linear models were applied to estimate the number of individuals missing from lists of cases obtained from Primary Care Centres, blind association (ACAPO) and from hospitals (the PCVIP-study). Log-linear models were used to estimate the crude prevalence and the category specific prevalence of VI. Causes of VI were obtained from the PCVIP-study.

Results
Crude prevalence of VI was 1.97% (95%CI=1.56-2.54), and normalized prevalence was 1% (95%CI=0.78-1.37). The age-specific prevalence was 3.27% (95%CI=2.36-4.90), older than 64 years, 0.64% (95%CI=0.49-0.88), aged 25-64 years, and 0.07% (95%CI=0.045-0.13), aged less than 25 years. Prevalence amongst females was 1.3x higher than amongst males. The five leading causes of VI were Diabetic Retinopathy, Cataract, Age-related Macular Degeneration, Glaucoma and Disorders of the Globe.

Conclusion
The prevalence of VI in Portugal was within the expected range and in line with other European countries. A significant number of cases of VI might be due to preventable cases and, therefore, a reduction of the prevalence of VI in Portugal seems possible. Women and old people were more likely to have VI and, therefore, these groups require extra attention. Future studies are necessary to characterize temporal changes in prevalence of VI in Portugal.

Keywords
Prevalence, vision impairment, low vision, blindness, capture-recapture, cataract, diabetic retinopathy, age-related macular degeneration
Introduction

Vision impairment (VI) leads to a significant loss of quality of life mostly due to activity limitations, loss of independence and difficulties to find jobs [1-6]. Because VI leads to a significant burden it is important to have regular vigilance (estimates) of cases of VI so that the quality of eye care and events such as diseases that may be leading to more cases of VI can be detected, evaluated, monitored and, eventually, vision loss can be prevented [7, 8]. One example of initiatives based on prevalence is VISION 2020 - an action of World Health Organization and the International Agency for the Prevention of Blindness, aiming to prevent and monitor VI and promote vision rehabilitation worldwide [9]. Recent estimates indicate that VI remains a significant health problem in Europe; although, in some countries reliable and updated information is lacking [9].

In 2020, in Western Europe, it has been estimated that there were 15 400 000 (95% CI, 13 900 000–16 900 000) people with moderate or severe VI [9]. However, the prevalence of VI and the methodology for the estimation varies significantly from country to country. For example, a population-based study conducted in Denmark in 2016 defined VI as best corrected visual acuity worse than 20/40 in the better-seeing eye. The study involved people aged 20 to 94 years and found a prevalence of 0.4% (95% CI, 0.2–0.7) [10]. A very different estimation with significantly different values was performed France in 2005 [11], in this study VI was self-reported and the prevalence was 1.95%. In 2007 and for the population aged 50 years or older, a study from Hungary reported a prevalence of 0.5% (95% CI, 0.2–0.7) for severe VI and 5.1% (95% CI, 4.3–5.9) for moderate VI [12]. These numbers are often hard to compare due to different age categories included and recruitment methods used; although, they point to differences among European nations.

Differences in prevalence of VI in Europe, as summarized in Table 1, may be due to not only study design but also, for example, due to differences in disease prevalence. VI and blindness in Western Europe is mostly linked to age-related eye diseases, in Germany, for example, that corresponds to 70% of all cases of blindness [13]. In Scotland, the leading causes of VI are Age-related Macular Degeneration (AMD), Glaucoma, Diabetic Retinopathy (DR), Myopic Degeneration, and Optic Atrophy [14]. Differences in disease prevalence and disease severity are associated with factors such as prevention and access to treatments [8]. Inequalities in accessing treatments can be seen even within a single country such as Portugal where unequal access to anti-VGEF injections was detected [15]. This makes it important to
investigate prevalence and causes of VI as detailed as possible at national and regional levels. One method to study prevalence when cross-sectional studies of the population are unavailable is called capture-recapture (CR).

CR methods have been used to estimate the prevalence of several eye conditions [16-24]. CR methods is a methodology that can overcome the problem of cases that are never captured by, for example, registers for the visual impaired [25-27]. For a detailed description on how to use CR methods we recommend reading our review about the method [28]. Due to the lack of information about the prevalence of VI in Portugal, we conducted a study with CR methods using data from different sources. The aim of this study was to estimate the prevalence and the main causes of VI in Portugal using CR methods.

== Table 1: Prevalence of vision impairment in European countries ==

### Methods

Information about people with VI was obtained from different sources in the Norwest of Portugal during a period spanning years 2014-2015. The geographical coverage included 42 municipalities from two provinces: Minho, population density = 241.1 inhabitants/km² and Douro Litoral, population density = 742.4 inhabitants/km², national CENSUS 2011 [29]. The study was conducted in accordance with the tenets of the Declaration of Helsinki, approved by the local ethics committees of the participating hospitals and by the ethical committee for Life Sciences and Health of the University of Minho, Ref. SECVS-084/2013; data protection process numbers 9936/2013 and 9793/2017.

Possible sources of patients with visual acuity in the better eye of 0.5 decimal (0.30logMAR) or worse and/or visual field less than 20 degrees were investigated [30]. The first source were Primary Care Centres that were used for list L1. This list contained subjects that applied, for example, for medical certificates of VI. According to the Portuguese law people with a level of impairment of 60% or more are entitled to, amongst other, tax exemption, completely free health care or early retirement [31]. As an example, to get a degree of 60% or more from vision only, one eye must have no measurable acuity and the other can have acuity up 0.2 decimal [32] Although, for this certificate all types of impairments can be combined, e.g. vision and motor impairments, to reach the final score. Because of that, cases mapped as having VI were analysed and only those with field or acuity
matching the inclusion criteria were included in this study. The second source used was an
association for the visually impaired named ACAPO and their records were used in the
second list L2. To be member of ACAPOI people must be visually impaired (low vision or
blind).

The third list L3 was obtained from the PCVIP-study, a hospital-based study whose
aim was to determine prevalence, causes and costs of VI in Portugal [33-35]. The study
gathered demographic, clinical, and socioeconomic information of people with VI.
Participants were selected among patients attending ophthalmologists’ appointments at four
Portuguese public hospitals: Hospital de Braga, Hospital Senhora da Oliveira-Guimarães,
Hospital de Santa Maria Maior-Barcelos and Centro Hospitalar e Universitário de São João -
Porto. The initial database included people with acuity 0.5 decimal (0.30logMAR) or worse,
to make compatible with the definition of VI in the ICD9 [30] and with the acuity in the other
lists only cases with visual acuity below 0.3 decimal in the better-seeing eye were used for
the estimation of prevalence.

All lists had variables that allowed assessment of repeated cases by using a string or
combination of strings that form identifiers or “tags”. Information available included: initials,
date of birth, sex and municipality. The list from the hospitals also included information
about the cause of VI. An example of a tag could be JS130519802 where JS are the initials
(first and last name), 13051980 is the date of birth (13-05-1980) and the last digit (2) defines
sex – 2 is a female in the example given. By matching the identity strings (tags) of the three
lists, it was possible to ascertain the number of individuals present in all three lists and the
number of individuals present at any combination of two lists.

To be used in CR lists need to be obtained at approximately the same time, or based
on different sources that represent approximately the same population [36]. In addition, to
obtain reliable results with CR certain assumptions need to be meet: 1) the sources of lists are
independent - this implies that the probability of a subject being in both list A and list B
equals the product between the probability of being in A alone and the probability of being in
B alone [37], 2) the probability of association within each source (catchability) is equal for all
individuals - the probability may vary from one list to another, or be constant overall [37, 38],
3) the population is closed (no births, deaths or migrants). These assumptions are restrictive
and, when applied to medical conditions, are unlikely to be strictly followed. Log-linear
models are one way of handling, for example, lists that are not completely independent [37].

Log-linear models were applied to estimate the number of individuals missing from
all three lists [38]. Log-linear models result from the application of Poisson regression
models to Table 2, the table summarizes all possible capture history for any case listed. The capture history is illustrated in Figure 1. The logarithm of the count in each cell of the table is modelled as a linear function with terms indicating the presence or absence in the lists and terms modelling possible pairwise dependences between lists. After choosing the best possible model we obtained an estimate of the dimension of the hidden population and consequently an estimate of the number of individuals with VI. The same procedure was used to compute category specific prevalence according to age and sex. Within each category several models were applied to sub-lists obtained from the main lists.

**Results**

The total number of inhabitants in the geographical area covered by the current study was 3,010,964. The list from Primary Care Centres (L1) had 208 cases (52% females) with a mean age of 60 years (SD=18.93). The list with the cases from ACAPO (L2) had 878 cases (43% females) with a mean age of 54 years (SD=18.0). The list from the Hospitals (L3) had 4,272 cases (58% females) with a mean age of 74 years (SD=18.0). The Venn diagram in Figure 1 shows the intersection between lists obtained from comparisons between identity strings. Figure 1 shows that, for example, 39 individuals were in L3 and L1 and were not in L2; 13 individuals were in all three lists; 4,161 individuals were only in L3. Table 2 provides the possible capture histories and the number of individuals with that history. For example, a subject has a capture history $1 1 0$ when she or he was in L1 and L2 but not in L3.

**Figure 1: Venn diagram representing the intersection between the three lists**

**Table 2: Number of individuals presenting each possible capture history**

Log-linear models admitting possible list dependence scenarios were applied to model the counts in Table 2. The model is expected to estimate the value of $x$ (see also Table 2) that corresponds the number of individuals with capture history $0 0 0$. That is, the size of the hidden population or the number of individuals not captured by any of the three lists. The estimate of total number of people with VI ($N$) was given by the expression: $N=x+13+38+39+59+118+768+4162$, the value of $N$ changes from model to model because the estimates obtained to the unknown $x$ value. All possible list dependence scenarios were
considered resulting in seven models summarized in Table 3. Code used to implement these models in R Statistics (v3.6.1), package Rcapture [39, 40] is provided in Appendix A.

Table 3: All possible log-linear models and resulting prevalence estimates

The list dependence scenario L1L2 and L1L3 generated a model fitting the data well, goodness of fit test \( p = Pr(\chi^2 \geq 0.009) = 0.92 \). It is also the model with the lower value of AIC. According to the model the crude prevalence of VI as estimated in this study was 1.97\% (95\% CI, 1.56-2.54). The normalized prevalence was 1\% (95\% CI, 0.78-1.27).

Completeness, that is, the proportion of the population with VI that has been captured by our three lists, assuming that the size \( N \) of the population with VI was 59,316, was 9\%. Completeness was computed using the formula below, in the formula, \( n_{100} \) is the number of cases with capture history (1 0 0) and the meaning is the same for all other parcels such as \( n_{010} \) in the denominator of the fraction.

\[
\frac{n_{100} + n_{010} + n_{001} + n_{111} + n_{101} + n_{011} + n_{110}}{N} \times 100
\]

\[
= \frac{118+768+4161+13+39+59+38}{93,316} \times 100 \approx 9\%.
\]

Table 4 shows category specific prevalence according to age and Table 5 category specific prevalence according to sex. To run new log-liner models for each category we divided the initial lists according to the desired categories. Subsamples for each category were used to generating new Venn diagrams. Log-linear models for each subsample were set as given in Table 3, that means seven different dependency scenarios for each, for example, age category. The best model was chosen using criteria of AIC and p-values.

Table 4: Age-specific prevalence

Table 5: Sex-specific prevalence

Figure 2 illustrates the distribution of causes of VI. This information was available from L3 (from the hospitals), causes were classified according to the ICD9. DR was the most common cause of VI with 31\% (95\% CI, 29 - 32) of the cases in L3, followed by Cataract 15\% (95\% CI, 14 - 17), AMD 14\% (95\% CI, 13 - 15), Glaucoma 10\% (95\% CI, 9 - 11) and Disorders of the globe (DG) 5\% (95\% CI, 4 - 6). Figure 2 also shows the causes per age group and confidence interval for each cause are given in the figure legend.
Discussion

The current study investigated the prevalence and causes of VI in the north-west of Portugal. Crude estimates of prevalence point that 2 out of 100 inhabitants of the Portuguese north-western population suffer from VI. Category-specific prevalence by age and by sex revealed higher prevalence among older people and among women. The top causes of VI included DR and Cataract, information about causes of VI was available only from cases detected at hospitals.

Prevalence of VI for the general population was within the expected values. Our results are in line with those reported in neighbour countries such as Spain [41]. This was an expected result because both countries have similar populations. Our results were also in line with a French study reporting a prevalence of VI of 1.95% [11]. A study from Iceland reported a prevalence of 0.96% (95% CI, 0.37–1.55) [1] that is similar to our study if we consider the normalized prevalence instead of the crude prevalence. Another study conducted in 2000 in Copenhagen, urban Denmark, also found a value for prevalence close to 1% [42]. In contrast, a study from 2016 in rural Denmark found a prevalence of 0.4% (95% CI, 0.2–0.7) [10] which is similar to what has been reported in Germany 0.37% (95% CI, 0.28–0.49) [7]. Recent studies show that the incidence of VI in countries like Germany has been reducing and, therefore, more recent studies are likely to report lower prevalence of VI than older studies [43]. One possible explanation for slightly higher values of prevalence of VI in our study in Portugal can be the prevalence and incidence of, for example, diabetes and DR [44, 45]. In other words, some European countries seem better at preventing vision loss from common eye diseases such has DR and removing it from top cause of VI, while in Portugal at the time of our study DR was still the top cause of VI [46]. In other parts of Europe such as Hungary prevalence of VI was higher than our study, here VI is expected affect more than 5% of the population [12]. In short, prevalence of VI in Portugal was similar to neighbour countries, but slightly higher than in countries with, possibly, better preventive mechanisms of vision loss. Our results point that is possible to reduce the prevalence of VI in Portugal, the exact strategies can be inspired from European countries reporting lower prevalence of VI.

VI was more common among elderly people, it increased from about 7 out of 10,000 in the population under 25 years to 60 out of 10,000 in the age range 25-64 years and about
300 out of 10,000 in the population with 64 or more years, these findings are in line with other studies [7]. A study in Denmark found that VI was 9x more prevalent amongst people with more than 64 years than amongst people in the age range 20-64 years [42]. Our results for the older population are also in line with the estimates from a recent meta-analysis estimating the prevalence of VI in people 55 years or older in European countries. The study that included data from Portugal, estimated an overall prevalence of VI for those above 55 years close to 2.75% [47, 48]. For age under 25 years, prevalence of VI in our study was low and in line with several other studies [49-51]. For example, our results were similar to data available from Sweden, in 1997 the age-specific prevalence of VI as 10.9/10,000 amongst people under the age of 19 years [51]. A more recent study from China that investigated VI amongst pre-school children also found a similar prevalence [52]. There was a good agreement between our results and similar studies, small differences might be due, among other factors, to temporal changes in prevalence of VI and the age-range criteria.

Prevalence of VI among females was 1.3x higher than the prevalence among males, this result is in line with the trend reported in a recent meta-analysis covering European countries [47]. These results are also consistent with studies from Germany [7], VI among females was 1.4x higher than among males, and from Spain [41], prevalence amongst females was 1.7x higher than amongst males. The female-to-male ratio is expected to vary from 1.1 is Sub-Saharan Africa to 1.25 in Europe [53]. Causes for this female-to-male ratio above 1 are likely to include factors such as gender inequalities in access to health care [54].

The top two causes of VI in our study were DR and Cataract. Information about causes of VI in our study was available from hospitals and that might increase the frequency of cases with treatable diseases such as the top two causes. The main causes of VI in Europe are diverse [55] and we provide a summary of some studies in Table 6 [7, 14, 42, 56, 57]. Studies compiled in Table 6 show that, for example, DR was the top cause of VI only in our study. We can speculate that the main reason was that when our study was conducted the preventive effects of DR screening were not yet visible in Portugal and, therefore, the number of cases of VI caused by DR was high [44]. This contrasts with other countries such as Germany or Denmark where DR appears down in the list of main causes of VI. Probably preventive DR measures were implemented earlier than in Portugal [44]. While in some studies DR remains in second place as cause of VI [58] it seem that the trend is to go further down in the list [59, 60]. Our second cause of VI, Cataract, has also been reported as important cause of VI in Denmark, Canada and the UK [10, 61, 62]. We believe that, for example, in Denmark, the high number of cases of Cataract causing VI was due to the
inclusion criteria with acuity 20/40. In many countries this is also the criteria to undergo cataract surgery. In our study we believe that a considerable percentage of cases of VI caused by Cataract was due to long queues for surgery at the time of our study [63].

Table 6: Causes of visual impairment in 6 European countries, including Portugal

In this study we used capture-recapture models to investigate prevalence of VI. Some models showed high quality of fit which gives credibility to the prevalence values that we obtained. The best models were the ones with the list dependences Primary Care Centres/Hospitals and Primary Care Centres/Blind Association, it is important to recapitulate that CR methods give the estimates for the non-captured cases or hidden population unavailable from our data sources. The Primary Care Centres/Hospitals dependence is understandable because medical certificates of VI require a report from an ophthalmologist that, most likely, is the assistant physician at the hospital. The Primary Care Centers/Blind Association dependence is explained by the fact that the Blind Association recommends their members to get a medical certificate of VI. The fact that completeness was about 9% is a limitation of our study, to solve this we needed more information from Primary Care Centres. This limitation may be addressed in future studies with better standardized digital records that allow more efficient anonymous data sharing.

In conclusion, the results of the current study showed that prevalence of VI in Portugal was within the expected range and in line with other neighbour countries. A significant number of cases of VI detected was due to preventable causes, in other words, a reduction of cases of VI in Portugal is possible with improved access to eye care and effective diseases monitorization. In addition, basic and comprehensive vision rehabilitation is necessary to support people with VI [64]. Future studies are necessary to characterize temporal changes and the efficacy of public health measures such as DR screening at reducing prevalence of VI.

Funding

This study was supported by FCT (COMPETE/QREN) grant reference PTDC/DPT-EPI/0412/2012 in the context of the Prevalence and Costs of Visual Impairment in Portugal: a hospital-based study (PCVIP-study). PLR is funded by FCT (COMPETE/QREN) grant

Table 3: All possible log-linear models and resulting prevalence estimates. When we write, for example, L1L2 we are indicating that the model assumed dependence between L1 and L2. N- and N+ represent lower and upper estimates of N according to a 95% confidence interval. P-values test the hypothesis of the model fitting well (a value above 0.05 is indicative that the difference between the model predictions and the data is not statistically significant) the data and the Akaike’s Information Criteria (AIC) is a criterion to choose between models by considering a balance between the number of fitted parameters and the maximum likelihood. Lower AIC values indicate better fitting of the data by the model.

Table 4: Age-specific prevalence. P-values test the hypothesis of the model fitting well (a value above 0.05 is indicative that the difference between the model predictions and the data is not statistically significant) the data and the Akaike’s Information Criteria (AIC) is a criterion to choose between models by considering a balance between the number of fitted parameters and the maximum likelihood. Lower AIC values indicate better fitting of the data by the model.

A – Total sample

B – Age less than 25

C – Age 25-64 years

D – Age more than 64 years

Figure 2: Distribution of causes of visual impairment. ORD = Other retinal disorders; OND = Optic nerve disorders DG = Disorders of the globe DR = Diabetic Retinopathy AMD = Age-related Macular Degeneration RDD = Retinal detachments and defects. The top 5 causes were: for age less than 25 years, OND 8% (95% CI, 4 - 13), OND 7% (95% CI, 4 - 12), RDD 4% (95% CI, 2 - 9), DG 3% (95% CI, 1 - 8), ORD 3% (95% CI, 1 - 8); for age 25-64 years, DR 25% (95% CI, 22 - 28), DG 10% (95% CI, 8 - 12), Glaucoma 8% (95% CI, 7 - 11), Cataract 7% (95% CI, 6 - 9), Cornea 7% (95% CI, 6 - 9) and for age more than 64 years, DR 33% (95% CI, 32 - 35), Cataract 18% (95% CI, 17 - 19), AMD 17% (95% CI, 15 - 18), Glaucoma 11% (95% CI, 10 - 12), DG 4% (95% CI, 3 - 5).
Table 6: Causes of visual impairment in 6 European countries, including Portugal.
