Abstract—47 words

We document that three human-pathogenic zoonotic trematodes are introduced and widespread throughout southern California in their first intermediate host snail (*Melanoides tuberculata*). We highlight the need to consider these introductions from a public health perspective in California and elsewhere in the United States the snail has invaded.

Foodborne trematodiases are among the most important neglected infectious diseases of the world, with up towards a billion people estimated to be at risk (Hotez et al. 2008, Keiser & Utzinger 2009, Fürst et al. 2012). These diseases involve a wide range of pathologies, including abdominal pain, chronic cough, hepatomegaly, bile-duct cancer, and brain hemorrhage (Chai et al. 2005, Keiser & Utzinger 2009, Sripa et al. 2010). Foodborne trematodiases result from infection by trematode flatworms that transmit to people who eat second intermediate host organisms carrying infectious metacercariae, which, in turn, originate from larval stages using first intermediate host snails. Foodborne trematodiases have not historically been a major public health concern in the United States, probably given a lack of snails known to transmit injurious trematodes. However, the introduction of one such snail in recent decades opens the door for the emergence of foodborne trematodiases in the United States.
The snail *Melanoides tuberculata* serves as first intermediate host for at least 11 human-infecting trematode species (Pinto & Melo 2011). Although native to Asia and Africa, the snail has been introduced around the world, including in the Americas from the United States to southern Brazil (Murray 1971, Facon et al. 2003, Coelho et al. 2018, CABI 2020, Chalkowski et al. 2021). At least three human-pathogenic, zoonotic trematodes have been co-introduced with the snail in the Americas (see Scholz et al. 2001, Pinto & Melo 2011 and refs therein), including reports in the continental United States of all three species in Texas (Nollen & Murray 1978, Mitchell et al. 2000, Tolley-Jordan & Owen 2008), one in Arizona (Church et al. 2013), and another in Utah and Florida (Mitchell et al. 2005). However, *M. tuberculata* is much more widespread throughout the United States (Chalkowski et al. 2021) than the few places the trematodes have been reported. Because these trematodes are dispersed by birds, there is a high probability that the parasites will also be much more widespread in the United States than currently recognized. Despite this possibility, and in contrast to elsewhere in the Americas (e.g., Pulido-Murillo et al. 2018, Lopes et al. 2020), there appears to have been no substantial consideration from a public health perspective of the introduction of *M. tuberculata* and its suite of trematodes in the United States (but see Murray (1971) and Chalkowski et al. (2021)). Here, we document that the snail, its three human-pathogenic trematodes known from elsewhere in the Americas, and several other trematodes potentially introduced to the Americas, are all established in areas of possibly high exposure risk throughout southern California, one of the most populous metropolitan areas in the United States.

In September 2019, we discovered several *M. tuberculata* at a San Diego fishing locality that were infected with *Haplorchis pumilio*, a foodborne human-pathogenic trematode. The finding was surprising because, at that time, not even the snail was reported in the literature as being present in California, nor was it included in the California Department of Fish and Wildlife’s list of invasive invertebrates (https://wildlife.ca.gov/Conservation/Invasives/Species) (but now see Chalkowski et al. 2021). However, observations and data on GBIF.org and iNaturalist.org revealed that *M. tuberculata* was widespread throughout southern California (Figure 1). Given the high probability that the snail’s trematodes would also be widespread, we initiated a broader sampling of southern California. We restricted our focus to freshwater fishing localities, as the most medically important trematodes transmitted by *M. tuberculata* elsewhere in the Americas are fishborne.

We have thus far hand or dip-net collected live *M. tuberculata* from the shallow waters (<1.2 m) of five southern California fishing localities (Figure 1, Table 1). We dissected snails within 48 hours of collection to identify trematode infections, using microscopical examination to compare worm morphology to literature descriptions (see refs in Pinto & Melo 2011). We extracted genomic DNA from one to five cercariae per infected snail in 1 µL of a 2 mg mL⁻¹ proteinase K solution (Qiagen), then amplified 28S rDNA using existing primers (dig12 and 1500R from Tkach et al. (2003)) and PCR protocols (slightly modified from Tkach et al. (2003)). We examined PCR products on a 1x TBE agarose gel before shipping successful products to Eton Biosciences (San Diego, CA) for Sanger sequencing services. We used MEGA X (Stecher et al. 2020) to trim the trace files by eye prior to a discontiguous megaBLAST comparing each sequence to all 28S Platyhelminthes sequences present in GenBank (http://www.ncbi.nlm.nih.gov) as of September 2021. We archived newly generated sequences in GenBank (Table 1).
Figure 1. The introduced snail, *Melanoides tuberculata*, and three of its human-pathogenic trematode parasites are widespread throughout southern California. The 25 sites with research-grade *M. tuberculata* observations from iNaturalist.org (bottom points of red inverted triangles) are well-interspersed among the 55 fishing sites (blue circles) listed by the California Department of Fish & Wildlife at elevations likely suitable for *M. tuberculata* survival. Surveyed sites are marked by dashed lines leading from pie charts: K Hahn = Kenneth Hahn State Recreation Area (Los Angeles Co.), Eisen = Eisenhower Park (Orange Co.), Murray = Murray Reservoir (San Diego Co.), Chollas = Chollas Lake Park (San Diego Co.), Santee = Santee Lakes Recreation Preserve (San Diego Co.). Pie charts indicate parasite prevalence at each surveyed site: green = *Haplorchis pumilio*, gold = *Philophthalmus gralli*, purple = *Centrocestus formosanus*, gray = other non-human-pathogenic trematodes, white = uninfected snails. Photographs of heat-stunned, unstained cercariae of each human-pathogenic trematode are coded to their respective color on the pie charts. Scale bar = 100 µm.

*M. tuberculata* harbored introduced trematode infections at each of the five localities. Two trematode species morphologically and genetically (99.8-100%) matched the fishborne trematodes *Haplorchis pumilio* and *Centrocestus formosanus*, which are introduced elsewhere in the Americas (Mitchell et al. 2000, Scholz & Salgado-Maldonado 2000, Tolley-Jordan & Owen 2008, Pulido-Murillo et al. 2018, Lopes et al. 2020). *H. pumilio* was the most common trematode, being present at each locality at relatively high prevalences (Table 1, Figure 1). These introduced heterophyids have garnered attention given the impacts on second intermediate host fish (e.g., Mitchell et al. 2000, Mitchell et al. 2005, Huston et al. 2014). However, like other heterophyids, the adult stages of these trematodes cause a wide range of pathologies in humans, sometimes possibly being deadly (Keiser & Utzinger 2009, Sripa et al. 2010, Chai & Jung 2017). People are infected when eating raw, undercooked, or pickled second intermediate host fish, or via utensil contamination. Because these parasites occur in fishing localities, can infect a wide range of fishes, and fish are commonly eaten in California, including uncooked as ceviche, poke, and sushi (unpub. obs.), there is a real possibility for *H. pumilio* and *C. formosanus* to cause foodborne trematodiasis in California and elsewhere in the United States.
Table 1. Prevalences (±95% CI) of human-infecting and other trematode species in the introduced first intermediate host snail *Melanoides tuberculata* from our initial sample sites in southern California, USA.

Total no. snails ‡‡ 54 97 296 19 13 479

*95% CIs calculated via Wilson Score method.
† Sampling dates (all in 2021): Murray (5 May, 20 Jun), Santee (10 Jun), Chollas (23 Jun, 12 Jul), Eisenhower (16 Jul), Kenneth Hahn (1 Jul).
‡ Human infecting. GenBank accession nos.: *H. pumilio* (OK335796-OK335799), *P. gralli* (OK335800-OK335802), *C. formosanus* (OK335803-OK335804)
§ A large, white renicolid not previously reported from *M. tuberculata*, at least in the Americas. Renicolids infect the kidneys of birds as final host. GenBank accession nos.: OK335805-OK335806
¶ A brownish renicolid, potentially identical to *Cercariae Indicae XIV* described from India (see ref in Pinto & Melo 2011), which may be identical to the “*Renicola* sp.” in Brazil of ref (Pinto & Melo 2012). Renicolids infect the kidneys of bird final hosts. GenBank accession nos.: OK335805-OK335806
# A renicolid xiphidiocercaria, morphological match with *Cercaria Levantina* 12 described from Israel (see ref in Pinto & Melo 2011). Renicolids infect the kidneys of bird final hosts.
** Morphologically and genetically (99.8%) matches “Lecithodendriidae gen. sp.” of ref (Lopes et al. 2021), which may be introduced to the Americas (Lopes et al. 2021). Likely infects bats as final host. GenBank accession nos. OK335156-OK335157.
†† An “Armata” cercaria not previously reported from *M. tuberculata*, at least in the Americas. Likely infects an ectothermic vertebrate as final host.
‡‡ Nine double infections were included in the counts, causing column totals to not always match the total number snails examined.

The other encountered human-pathogenic trematode morphologically and genetically (99.6-100%) matched *Philophthalmus gralli*, which is also reported from *M. tuberculata* in Arizona (Church et al. 2013), Texas (Nollen & Murray 1978) and farther south in the Americas (Diaz et al. 2002, Chalkowski et al. 2021). *P. gralli* infects humans via ingestion of aquatic hosts harboring metacercariae or by direct contact with swimming infectious cercariae. *Philophthalmus* species can infect the eyes of humans and cause conjunctivitis (Gutierrez et al. 1987), with a recent case in Texas (Sapp et al. 2019). *P. gralli* can also cause substantial problems in captive birds (e.g., Greve & Harrison 1980, Church et al. 2013). Although *P. gralli* may be of less human health concern than the above two species, it was the second most common trematode (Table 1) among the three introduced human-infesting trematodes transmitted by *M. tuberculata* in California and elsewhere in the United States.
We detected five additional trematode species, including two not previously reported from *M. tuberculata* in the Americas, all of which are possibly introduced (Table 1). These species are likely of little direct public health concern given their probable life cycles, but they may be of veterinary interest (Table 1). However, if they do represent novel introductions to the Americas, their presence highlights that additional foodborne trematodes transmitted by *M. tuberculata* in its native range may also be introduced here. Such trematodes include severely pathogenic trematodes such as the carcinogenic human liver flukes (*Clonorchis sinensis* and *Opisthorchis* species), and the lung fluke (*Paragonimus westermani*).

Hence, several factors suggest the possible emergence and even ongoing presence of foodborne trematodiases in California: (1) the introduced *M. tuberculata* snail is widespread, including at localities where people catch fish for eating; (2) the snail carries at least three of its human-pathogenic trematodes, including two that are fishborne; and (3) the snail also carries several other potentially introduced trematodes, indicating the possibility that additional human-pathogenic trematodes are already introduced or may be introduced in the future. Taken together, these factors clearly call for additional consideration of *M. tuberculata* from a public and veterinary health perspective in California and wherever else the snail is present in the United States.
