Brief summary: SARS-CoV-2 mRNA vaccination induces greater antibody response in older females than males, and age and frailty reduce responses in males only. These effects are eliminated by a third vaccine dose, highlighting the need for third dose coverage, especially in older males.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.
Abstract

Background: Male sex and old age are risk factors for severe COVID-19, but the intersection of sex and aging on antibody responses to SARS-CoV-2 vaccines has not been characterized.

Methods: Plasma samples were collected from older adults (75-98 years) before and after three doses of SARS-CoV-2 mRNA vaccination, and from younger adults (18-74 years) post-dose two, for comparison. Antibody binding to SARS-CoV-2 antigens (spike protein [S], S-receptor binding domain [S-RBD], and nucleocapsid [N]) and functional activity against S were measured against the vaccine virus and variants of concern (VOC).

Results: Vaccination induced greater antibody titers in older females than males, with both age and frailty associated with reduced antibody responses to vaccine antigens in males, but not females. ACE2 binding inhibition declined more than anti-S or anti-S-RBD IgG in the six months following the second dose (28-fold vs. 12- and 11-fold decreases in titer). The third dose restored functional antibody responses and eliminated disparities caused by sex, age, and frailty in older adults. Responses to the VOC were significantly reduced relative to the vaccine virus, with older males having lower titers to the VOC than females. Older adults had lower responses to the vaccine and VOC viruses than younger adults, with disparities being greater in males than females.

Conclusion: Older and frail males may be more vulnerable to breakthrough infections due to low antibody responses before receipt of a third vaccine dose. Promoting third dose coverage in older adults, especially males, is crucial to protecting this vulnerable population.
Introduction

The disproportionate burden of COVID-19 in older adults was recognized early in the pandemic [1-3]. The phase III trials for the two mRNA vaccines (mRNA-1273 and BNT162b2) revealed high efficacy in older adults [4, 5], for whom immunosenescence is thought to impair vaccine-induced immune responses [6]. Clinical trials, however, often fail to represent the oldest and frailest subset of the population. Accordingly, widespread use of the vaccine in long-term care facility residents revealed that old age is a risk factor for poor antibody responses [7-9].

Male sex also is a significant predictor of severe COVID-19 outcomes at older ages [10-14]. There is extensive evidence that the effects of aging on the immune system differ between the sexes, including that immunosenescence occurs at a slower rate in females than males [15, 16]. The implications of biological sex are evident in the response to repeated seasonal influenza vaccination in older adults, where pre-vaccination titers decrease with age in males but not in females, suggesting that older females enter each influenza season with greater immunity than their male counterparts [17]. In the context of SARS-CoV-2 vaccines, however, studies have failed to provide sex-disaggregated data within each age group [18, 19], and little is known about how biological sex may modify the effects of age, and age-related factors like frailty, on vaccine immunogenicity. Here, we investigate sex differences and sex-specific effects of aging in the humoral immune response to the vaccine virus and variants of concern (VOC) induced by three doses of a SARS-CoV-2 mRNA vaccine in a cohort of adults above 75 years of age. We illustrate that the age- and frailty-associated declines in antibody responses occur to a greater extent in males than females.
Methods

Cohorts

Older adults (75-98 years) were recruited from the Johns Hopkins Longitudinal Influenza Immunization Study of Aging over 75 years of age (JH LIISA 75+) cohort [17] (Table 1).

Individuals who had worsening or new-onset of immune-modulating conditions (e.g., rheumatoid arthritis, hematologic malignancies, or other cancers) or a previous diagnosis of COVID-19 were excluded. Participants came to the Johns Hopkins Bayview Medical Center, or study visits were conducted at participants’ homes, as needed. At pre-vaccination visits (Pre), frailty status was assessed using the Fried Frailty Phenotype [20] and a baseline blood draw was obtained. Subsequent receipt of two (primary vaccination series) or three doses of a SARS-CoV-2 mRNA vaccine, either mRNA-1273 or BNT162b2, was confirmed via vaccination cards, and blood samples were collected 14-30 days (i.e., average ≤ 1 month [M]) post dose 1 (<1M_PD1), 14-30 days post dose 2 (<1M_PD2), 90 (± 15) days post dose 2 (3M_PD2), 180 (± 15) days post dose 2 (6M_PD2), and 14-60 days post dose 3 (1M_PD3).

Younger adult healthcare workers from the Johns Hopkins Health System were also sampled as a comparison group. Recruitment of these younger adults has been reported elsewhere [21]. To be eligible for the present study, participants needed to be younger than 75 years, not have a history of COVID-19, and have two samples collected at least 90 days apart, with the first one collected at least 14 days after receiving the second dose of a SARS-CoV-2 mRNA vaccine. Due to low plasma volumes, these amples were not tested for ACE2-inhibition, and data are missing for antibody titration against antigens from VOC for some participants.
Exact sample sizes are included in figure legends. For both cohorts, written, informed consent was obtained from all participants, and the study protocols were approved by the Johns Hopkins School of Medicine Institutional Review Board.

**Laboratory methods**

Detailed ELISA and ACE2 inhibition methods can be found in the Supplemental materials. Briefly, plasmids expressing recombinant nucleocapsid (N), Spike (S), or S receptor-binding domain (S-RBD) of the vaccine strain and the Alpha, Delta, and Omicron variants of SARS-CoV-2 were engineered at Johns Hopkins as described previously [22] or obtained through the NCI Serological Sciences Network for COVID-19 [23] (Supplemental Table 1). Recombinant proteins were used to coat plates for indirect ELISA measuring plasma IgG against N, S, or S-RBD. Results were expressed as the log_{10}-transformed area under the curve (AUC) generated from ten three-fold serial plasma dilutions, as previously described [22]. The ability of plasma antibodies to inhibit ACE2 binding to S was measured using Meso Scale Diagnostics (MSD) V-PLEX SARS-CoV-2 ACE2 kits according to the manufacturer’s protocol at a dilution of 1:100 [24]. Data were expressed as the log_{10}-transformed concentration (μg/ml) of ACE2-inhibiting antibodies (ACE2iAb), which are equivalent to anti-S monoclonal antibodies. IgG binding to seasonal and epidemic β-coronavirus S proteins were measured using the multiplex chemiluminescent MSD V-PLEX COVID-19 Coronavirus Panel 3 (IgG) Kit according to the manufacturer’s protocol at a dilution of 1:5000.
Statistical methods

Longitudinal data in the older adult cohort were analyzed using mixed-effects models with random intercepts on the individual to account for repeated measures, and interaction terms between study timepoint (categorical) and sex (self-report), age (categorized based on terciles) and frailty status. Linear regression models including interaction terms between sex and age or frailty were used to investigate sex-specific effects at individual timepoints. To compare the older and younger cohorts, the number of days post-dose 2 was used as a continuous predictor and cubic splines were included to study non-linear relationships [25]. Cubic spline knots were placed at 30-, 100-, and 160-days post-vaccination, points chosen to approximately divide the data into quartiles. Mixed-effects models included an interaction term between time and cohort and were repeated separately for males and females. Differences between cohorts were tested at three sentinel points (14-, 90- and 180- days post dose 2). All p-values <0.05 were considered statistically significant. Analyses were performed in Stata 15 (StataCorp).

Results

Study population demographics

Eighty-six older adults were recruited from the Baltimore area, with three participants excluded from analysis due to high N titers (i.e., titer >180), suggesting prior infection (Supplemental figure 1). One additional participant was excluded from analysis due to evidence of severe immunosuppression, such that their responses could not be accurately captured in population-level models. Characteristics of the 82 participants included in analysis are detailed.
in Table 1. The population had more females (59%) than males, and a median age of 84 years. Most participants were classified as pre-frail (64%) and a greater percentage of males than females were frail. All participants received two doses of a SARS-CoV-2 mRNA vaccine, with the majority (70%) receiving BNT162b2. Sixty participants (73%) received a third vaccine dose at least six months after the second dose.

Demographic information for the younger adult cohort is provided in Table 2. Of 84 eligible participants from the affiliated study [21], three were excluded due to high anti-N titers (Supplemental figure 1). In the younger population included in analysis, there were more females than males (60% vs 40%), most participants were between 30 and 49 years of age, and a majority of samples were collected 21-43 days and 125-150 days after receipt of the second vaccine dose.

Older females mount greater responses to vaccination than older males

Among older adults, IgG binding to S and S-RBD of the vaccine strain increased significantly in response to the first two vaccine doses and then decreased significantly in the 6 months following immunization (p<0.001 for all comparisons; Figure 1A-B & D). Geometric mean titers (GMT) decreased 11- and 12-fold, for S and S-RBD, respectively, from <1M_PD2 to 6M_PD2 (Supplemental Table 2). Females mounted greater IgG responses to S and S-RBD relative to their baseline than males at all post-vaccination timepoints (p<0.02 for all comparisons, Figure 1A-B & D). Older females also had greater titers of IgG against S and S-RBD at each visit, and this difference was significant for anti-S IgG at <1M_PD1 (p=0.020) and at 3M_PD2 (p=0.026). After receipt of a third vaccine dose, anti-S and S-RBD titers increased
significantly in both males and females (p<0.001), leading to GMT that were 2- and 4-fold
greater than the post-dose 2 peak for S and S-RBD, respectively (Supplemental Table 2).

The functional ability of antibodies to inhibit S from binding to ACE2 followed similar
kinetics as anti-S IgG in response to the primary immunization series, but then decreased more
rapidly in the 6-months following immunization, resulting in a 28-fold decrease in GMT from
<1M_PD2 to 6M_PD2 (Figure 1C & Supplemental Table 2). By 6M_PD2, 79% of males and 77%
of females had undetectable ACE2iAb. Sex differences were apparent at all timepoints and
were significant at 3M_PD2, with females mounting stronger responses than males (p=0.046).
Post dose 3, all but one participant had detectable ACE2iAb, and the geometric mean was 7-
fold higher than the post-dose 2 peak (Supplemental Table 2). Despite differences in kinetics
over time between the binding and functional assays, the three readouts of humoral immunity
correlated well with each other (Supplemental figure 2). As expected, correlations became
weaker at the lower range of the ACE2-inhibition assay. Taken together, these data suggest that
older females mount stronger response to SARS-CoV-2 vaccination than males, and that a third
vaccine dose is necessary to boost functional antibody responses in this population.

The effects of age and frailty are greater in males than in females

We next assessed the overall and sex-specific effects of age on the humoral response to
vaccination. Among all older participants, age was significantly associated with reduced anti-S
IgG, anti-S-RBD IgG, and ACE2iAb in the six months following the primary vaccination series
(Figure 2A-C). This effect was largely driven by the oldest tercile of the population (≥88 years).
The percent of participants with undetectable ACE2iAb by 6M_PD2 increased from 67% in the
youngest tercile (75-82 years) to 85% in the oldest tercile. In sex-disaggregated analyses focusing on the 3M_PD2 timepoint (i.e., a time point when all study participants were represented), age significantly impaired responses in males, but not females, leading to statistically significant sex differences in the effect of age for anti-S IgG (p=0.025) and ACE2iAb (p = 0.001; Figure 2D-F). The trend of greater age effects in males than females was consistent at other timepoints following the primary immunization series (Supplemental figure 3A-F), and by 6M_PD2, 100% of males in the oldest age group, compared to 77% of females, had undetectable ACE2iAB. After receipt of a third dose, the effect of age was no longer significant in the overall population or within either sex, suggesting that a third vaccine dose eliminated sex and age disparities in vaccine-induced immunity (Figure 2A-C & Supplemental figure 3G-I). Frailty had an important overall effect, with frail participants mounting significantly weaker responses to vaccination than robust and pre-frail participants (Figure 2G-I). By 6M_PD2, 90% of frail participants had undetectable ACE2iAB, compared to 75% of pre-frail and robust participants. Like with age, the effect of frailty at 3M_PD2 was significant in males, but not females for all assays (Figure 2J-L). No significant sex differences in the effect of frailty were observed, however, and trends were less consistent over time (Supplemental figure 3J-R). The effect of frailty was also attenuated by the third dose but remained significant for ACE2iAb (p=0.005; Figure 2I). From these data, we conclude that the effects of age and frailty in older adults are largely driven by males, not females.
Antibody responses to VOC are reduced relative to the vaccine virus

The breadth of vaccine-induced immunity in older adults was assessed by measuring anti-S IgG to the Alpha, Delta, and Omicron variants. Antibody titers to the Alpha and Delta variants were similar to each other and were both significantly reduced relative to the vaccine virus (2-4-fold lower GMT, p<0.001; Figure 3A & Supplemental Table 3). Titers to Omicron were further reduced relative to the vaccine virus (>5-fold difference in GMT) and the Alpha and Delta variants (p<0.001 for all comparisons; Figure 3A & Supplemental Table 3). Differences between anti-S IgG to the vaccine virus and the VOC were attenuated at 1M_PD3 (fold difference in GMT <1.5 for Alpha and Delta and <4 for Omicron) but remained significant (p<0.0001 for all comparisons). At 1M_PD3, anti-Alpha S IgG was significantly higher than anti-Delta S IgG (p<0.001). ACE2iAb to the Alpha and Delta variants also tended to be lower than to the vaccine strain, but these differences were smaller in magnitude than for anti-S IgG and were not statistically significant at all timepoints (Figure 3B-C). In sex-disaggregated analyses, females had higher responses to the VOC than males, and this difference was significant for anti-Delta S IgG (p=0.038) and ACE2iAb against the Alpha variant (p=0.034) at 3M_PD2 (Figure 3D-E & Supplemental figure 4).

SARS-CoV-2 vaccination induces IgG responses to other β-coronaviruses

To investigate the cross-reactivity of the vaccine-induced humoral response, IgG titers to seasonal and epidemic β-coronaviruses were measured in the older adults. Anti-HKU1 IgG titers increased in response to the primary vaccination series, but fell by 3M_PD2 (Figure 4A). Titers of IgG recognizing OC43, MERS-CoV, and SARS-CoV-1 increased significantly in plasma
samples collected after SARS-CoV-2 vaccination and remained elevated above baseline levels for 6 months (Figure 4B-D). Furthermore, titers to all four β-coronaviruses were significantly elevated by the third vaccine dose (Figure 4A-D). Notably, IgG binding to the two seasonal β-coronaviruses (HKU1 and OC43) was elevated at baseline, indicating widespread exposure to these viruses in this population. Increased antibody titers against related β-coronaviruses following SARS-CoV-2 vaccination suggests possible “back-boosting”, as observed for influenza vaccines [26] and in response to SARS-CoV-2 vaccination in the general adult population [27, 28]. These results indicate that SARS-CoV-2 vaccination increases broad antibody responses to diverse β-coronaviruses in older adults.

Differences between older and younger cohorts are driven by males

To further investigate the sex-specific effects of aging, antibody kinetics against vaccine, Alpha, and Delta antigens were compared between the younger and older adult cohorts in the six months following the primary vaccination series. In the whole population, anti-vaccine S IgG was significantly lower in older than younger adults (p<0.001 at 14 days post-vaccination, p=0.004 at 90 days, and p=0.026 at 180 days) (Figure 5A). In sex-disaggregated analyses, differences between the older and younger adults were significant among males at all three sentinel points (p=0.004 at 14 days post-vaccination, p=0.005 at 90 days, and p=0.019 at 180 days), but only significant among females at 14-days post vaccination (p=0.004) (Figure 5B-D). In addition, the magnitude of the difference between the mean of the older cohort and the mean of younger cohort was consistently larger for males than for females across the three sentinel points (Figure 5D). Similar results were observed for anti-Alpha and Delta S IgG (Figure
There were no significant differences in the rate of waning between older and younger adults, suggesting that antibody kinetics are not age-dependent.

**Discussion**

In this longitudinal study, older adult females mounted stronger antibody responses to SARS-CoV-2 mRNA vaccination than older males, and age and frailty were associated with reduced responses in males but not females. While the kinetics of antibody waning in the six months following immunization were not age-dependent, older adults mounted weaker initial responses to vaccination, such that their antibody titers remained lower than younger adults throughout the follow-up period. A sex-specific effect of age was observed both within the older cohort and when comparing younger and older adults, in which age-associated reductions in humoral immunity were greater among males than females. In the older adult cohort, receipt of a third vaccine dose largely eliminated disparities caused by sex, age, and frailty in antibody responses, with the exception of ACE2iAb, which remained lower in frail compared to non-frail or pre-frail participants. The effect of age on SARS-CoV-2 vaccine responses has been studied [7-9, 29-33], but the sex differential impact of age has not been reported previously.

Furthermore, studies investigating frailty have not found an effect on antibody responses [34-36], but have reported that frailty increases the risk of post-vaccination breakthrough infection [37, 38], suggesting that the immunogenicity studies may have been under-powered to observe an effect of frailty or that lack of consideration of biological sex obscured the effect.

The inclusion of three measures of humoral immunity and four SARS-CoV-2 viruses allowed us to capture the breadth and depth of vaccine responses in this vulnerable population.
For measurement of functional antibodies, ACE2-inhibition assays are a strong surrogate of live virus neutralization [24, 39]. In terms of responses to VOC, the reductions in anti-S IgG to the Alpha and Delta variants observed in the older adults were similar to other reports in the general population [40]. For the Omicron variant, while reductions in live-virus neutralization in vaccinated serum from the general adult population have been reported, there were no reductions in anti-Omicron S IgG [41, 42]. Given the importance of neutralizing and non-neutralizing functions of IgG in conferring protection against SARS-CoV-2 [43, 44], the markedly lower anti-Omicron S IgG level in older adults, that persisted after receipt of a third vaccine dose, suggests that this population may be more vulnerable to disease caused by the Omicron variant than younger adults, and that reformulation of vaccines to target the Omicron variant would be beneficial.

Our study had several strengths and limitations. Some of the sex-specific effects observed were differences among males that were absent among females, without statistical evidence of a sex difference (i.e., non-significant sex interaction terms) [45]. It is important to note that our findings were generated from post-hoc analyses that were not necessarily powered to investigate sex differences, and conclusions are limited by small samples sizes in certain sub-groups. Given the small sample sizes, it is not surprising that statistically significant sex differences were not consistently observed. Particularly for age-based analyses, however, the consistency of trends between assays and timepoints, coupled with statistically significant sex differences in the effect of aging at 3M_PD2, lend credibility to the conclusion that the effects of age on antiviral antibody responses are driven by males. Further supporting these findings are similar sex-specific effects of age observed following seasonal influenza vaccination.
in both younger and older adults [17, 46]. While it is important to not over-interpret ‘within-
sex’ differences as ‘between-sex’ differences [47], there is considerable value in studying
differences within males or females [48, 49]. This is particularly true given the uniqueness of
the community-dwelling older adult cohort, which represent the ‘oldest’ old subset, and are
distinct from the population of long-term care facility residents that has been the focus of much
of the SARS-CoV-2 research in older adults.

There also were missing data in the older adult cohort, particularly at the <1M_PD1
timepoint. These missing data did not, however, depart from the missing at random
assumption, and thus multi-level models were used to account for missingness. Second, the
timing of sample collection was different in the older and younger cohorts. To account for this,
alyses that compared the two groups used days post-vaccination as a continuous variable.
Finally, we have not investigated the functional antibody responses to the Omicron variant, nor
have we included measures of cellular immunity. These analyses are on-going.

In conclusion, we report that both age and frailty impair antibody responses to the
primary series of SARS-CoV-2 vaccination in older males, and that these disparities are largely
eliminated by receipt of a third vaccine dose. Given that male sex is an important risk factor for
severe outcomes from COVID-19 [10-14], the finding that older and frail males may be
vulnerable to breakthrough infections due to low antibody responses, particularly before a
third vaccine dose is administered, is of considerable public health importance. These findings
emphasize that increasing third dose coverage among older males is crucial to protecting this
vulnerable population from SARS-CoV-2.

<sup>a</sup> Subset of eligible participants without evidence of prior infection who were included in analysis

<sup>b</sup> Eligible participants from affiliated study (ref) were <75 years of age, had remaining serum from 2 samples collected at least 90 days apart 14-200 days following 2 doses of an mRNA SARS-CoV-2 vaccine who did not report prior SARS-CoV-2 infection

<sup>c</sup> Participants with high (> 1:180) nucleocapsid titers, indicating prior infection, were excluded from analysis

<sup>d</sup> Percents are based on the number included in analysis in each column
Figure Legends

Figure 1. Older females mount greater humoral responses to SARS-CoV-2 mRNA vaccines than older males.

Anti-spike (S) IgG (A), S receptor-binding domain (S-RBD) IgG (B), and ACE2-inhibiting antibodies (ACE2iAb) (C) against the vaccine strain of SARS-CoV-2 were measured at six timepoints: pre-vaccination (n=82: 48 females, n=34 males), 14-30 days post dose 1 (<1M_PD1; n=23: 12 females, 11 males), 14-30 days post dose 2 (<1M_PD2; n=69: 41 females, 28 males), 3 months post dose 2 (3M_PD2; n=82: 48 females, 34 males), 6 months post dose 2 (6M_PD2; n=80: 47 females, 33 males), and 14-30 days post dose 3 (1M_PD1; n=60: 34 females, 26 males).

Differences between timepoints were tested using mixed-effects models with study timepoint as a dummy variable and random intercepts on the individual. Sex differences were tested using an expanded mixed-effects model that included a main effect for sex and an interaction term between sex and study timepoint. All point estimates are shown with error bars indicating the 95% confidence interval. All p-values <0.05 are reported in D, where blank cells indicate a p-value >0.05 and crossed out cells indicate that the comparison is reported elsewhere in the table. Dashed lines show the limits of detection.

Figure 2. Age and frailty impact the antibody response to SARS-CoV-2 mRNA vaccines in a sex-specific manner among older adults.

The effect of age on antibody kinetics is shown for Anti-spike (S) IgG (A), S receptor-binding domain (S-RBD) IgG (B), and ACE2-inhibiting antibodies (ACE2iAb) (C) against the vaccine strain of SARS-CoV-2. Data are shown for six timepoints: pre-vaccination (n=32 aged 75-82; n=28 aged...
Sex-specific effects of age at 3M_PD2 are shown separately for females (n=20 aged 75-82; n=15 aged 83-87; n=13 aged ≥88) and males (n=12 aged 75-82; n=13 aged 83-87; n=9 aged ≥88) (D-F). The effect of frailty on antibody kinetics is shown for the three assays at six timepoints: pre-vaccination (n=18 robust; n=53 pre-frail; n=10 frail), <1M_PD1 (n=6 robust; n=12 pre-frail; n=5 frail), <1M_PD2 (n=15 robust; n=45 pre-frail; n=9 frail), 3M_PD2 (n=18 robust; n=53 pre-frail; n=10 frail), 6M_PD2 (n=18 robust; n=52 pre-frail; n=10 frail), and 1M_PD3 (n=14 robust; n=39 pre-frail; n=7 frail) (G-I). are shown separately for females (n=10 robust; n=33 pre-frail; n=4 frail) and males (n=8 robust; n=20 pre-frail; n=6 frail) (J-L). The overall effects of age (A-C) or frailty (H-I) at each timepoint were tested using mixed-effects models including a main effect for age/frailty, an interaction term between age/frailty and study timepoint, and all p-values <0.05 are shown. At 3M_PD2, the effect of age (D-F) or frailty (J-L) in males and females, and sex-differences in these effects, were tested using linear regression models with interaction terms between sex and age or frailty, and all p-values are shown. Point estimates are shown with 95% confidence intervals, and dashed lines indicate the limit of detection.
Figure 3. Antibody responses to Alpha, Delta, and Omicron variants are reduced relative to the vaccine virus in older adults.

Anti-S (A), and ACE2-inhibiting (B) antibodies against the vaccine, Alpha and Delta strains of SARS-CoV-2 were measured post-vaccination, with symbols indicating point estimates and error bars indicating the 95% confidence interval. Differences in the responses between viral strains were measured using paired t-tests, and all p-values <0.05 are shown in C, where empty cells indicate p-value>0.05 and crossed-out cells indicate that the comparison was not tested. Sex-disaggregated data from the 3-month timepoint are shown, and significant sex differences are indicated by p-values (D-E).

Figure 4. Antibody responses against seasonal and pandemic β-coronaviruses are boosted by SARS-CoV-2 vaccination in older adults.

IgG specific to the spike proteins of the HKU1 (A), OC43 (B), MERS-CoV (C), and SARS-CoV-1 (D) were measured before and at five timepoints after receipt of a SARS-CoV-2 mRNA vaccine. Differences between timepoints were tested using multi-level models with study timepoint as a dummy variable and random intercepts on the individual to account for repeat measures. All point estimates are shown with error bars indicating the 95% confidence interval and asterisks indicate significant (p<0.05) increases relative to the pre-vaccination vaccination timepoint.
Figure 5. Differences between younger and older adults in antibody responses to the vaccine strain of SARS-CoV-2 are sex-dependent.

Plasma samples were collected from older adults at 3 timepoints after the primary vaccination series and from younger adults at 2 post-vaccination timepoints: 16-76 days post dose 2 (early) and 96-190 days post dose 2 (late). Differences in anti-vaccine strain S IgG levels over time were compared between all younger and older adults (A), males (younger: n=27 early; n=30 late) (B), and females (younger: n=48 early; n=48 late) (C), and summarized at three sentinel points (14-, 90- and 180-days post-vaccination) (D). Comparisons of the anti-Alpha S IgG response between the younger and older groups are shown for the whole population (E), males (younger: n=27 early; n=26 late) (F), and females (younger: n=39 early; n=34 late) (G), with differences summarized at 14-, 90- and 180-days post-dose 2 (H). Comparisons of the anti-Delta S IgG response between the younger and older groups are shown for the whole population (I), males (younger: n=27 early; n=26 late) (J), and females (younger: n=47 early; n=42 late) (K), with differences at summarized 14-, 90- and 180-days post-dose 2 (L). Kinetics were analyzed using mixed-effects models with fixed effects including days post-dose 2 as a continuous predictor with cubic B-splines (knots at 30-, 100-, and 160-days post-vaccination). Shaded areas indicate 95% confidence intervals (A-C, E-G, I-K). In D, H, and L, point estimates for the difference between cohorts are shown with 95% confidence intervals, such that confidence intervals that do not span the null value of zero are statistically significant.
