**Key words**
Nucleic acid detection, multiplex PCR, melting curve analysis, plasmodium, malaria

**Abstract**
Nowadays, malaria is still one of the major public health problems which commonly caused by four plasmodium species, especially in the epidemic of COVID-19 harboring similar symptoms of fever or fatigue, which easily result in misdiagnosis. The disadvantages of previous traditional detection methods, such as time-consuming, costly, complicated operation, strong professionalism, indistinguishable typing and so on, lead to the dilemma of difficulty to meet the clinical requirements of rapid, easy and accurate typing of common plasmodiums. Herein, we developed and maximally optimized a universal two-dimensional labelled probe-mediated melting curve analysis (UP-MCA) assay based on multiplex PCR for rapid and accurate typing of five plasmodiums, including novel human plasmodium, *Plasmodium knowlesi* (Pk), in a single closed tube following genome extraction. The assay showed the limit of detection (LOD) of 10 copies per reaction and can accurately distinguish plasmodium species from intra-plasmodium and other pathogens. In addition, we also proposed and verified different methods of fluorescence-quenching and two dimensional labelled tag for probes that are suitable for UP-MCA assay. Furthermore, its clinical performance was evaluated by 184 samples and showed sensitivity of 100% (164/164) and specificity of 100% (20/20) at 99% confidence interval, respectively, with the microscopy method as gold standard. Taken together, the UP-MCA system showed excellent sensitivity, specificity and accuracy for genotyping of plasmodium, and it meets the requirements of rapidity and convenience for plasmodium detection in clinical routine and has great potential for clinical translation.

**Introduction**
Malaria is a life-threatening disease caused by protozoan parasites, belong to the *Plasmodium* genus, which are transmitted to people through the bites of infected female anopheles mosquitoes. Approximately 229 million malaria cases were reported worldwide according to World Malaria Report 2020, causing an estimated 409,000 deaths in 2019. Although claim of local malaria elimination from some regions or countries authenticated by World Health Organization (WHO), there is still a great risk of imported malaria with the development of economy globalization and the aggravation of population immigration and emigration across regions or countries.

Commonly, there are four parasite species of *Plasmodium* genus known to cause human malaria, including *Plasmodium vivax* (Pv), *Plasmodium falciparum* (Pf), *Plasmodium ovale* (Po), and *Plasmodium malariae* (Pm). Additionally, *Plasmodium knowlesi* (Pk) derived from macaques was considered as the fifth species of *Plasmodium* causing malaria in humans (1) since large focus and description in 2004 (2). Clinically, different treatments and monitoring patterns would be taken after the judgment of different *Plasmodium* species (3). Therefore, timely, easy and accurate typing of *Plasmodium* is very important for countries or coastal cities of happening transactions or population mobility frequently over the world, especially imported malaria from *Plasmodium* high-burden regions.

Traditionally, microscopy, known as the gold standard for the diagnosis of clinical malaria, is professional interpretative and time-consuming, requires expertise gained by strict training and experience, and cannot effectively support large studies. Also, it is difficult in distinguishing *P. knowlesi* from *P. malariae* because of their morphological similarities (2, 4), while *P. knowlesi* results in severe and deadly malaria. Rapid diagnostic tests (RDTs) based on immune-chromatographic antigen detection have been implemented in some diagnostic laboratories as a supplement to microscopy (5). Although they are rapid, simple, and easy to interpret, RDTs target proteins specific to *P. falciparum* or *P. vivax* or those common to all *Plasmodium* species and cannot specifically differ *P. malariae*, *P. ovale*, and *P. knowlesi* (5, 6). Furthermore, diagnostic sensitivity (e.g., lacking sensitivity for some strains of *P. falciparum* and up to 50% of *P. knowlesi*) (7) and specificity (e.g., *P. vivax* in patients
with co-infections and high *P. falciparum* parasitemia levels) are variable widely for commercially available RDTs.

Conversely, molecular detection methods offer an attractive alternative approach. Commonly, PCR is a heat-dependent cycle amplification reaction that harbors ability of exponential amplification for original genome used as one of most important nucleic acid test method(8-10). Conventional PCR assays require post-handling, time-consuming and risk of cross-contamination. Although some real-time PCR assays have been described(11, 12), they cannot distinguish multiple plasmodium species in one-pot reaction mainly as a result of low fluorescent channel and throughput, with similarly limited evaluation of one or two plasmodium species samples. Additionally, clinical performance of specificity cannot be ensured since blood samples from patients with plasmodium are difficult to be obtained and infrequently tested. Recently, Plasmodium species detection assay based on isothermal amplification, such as loop-mediated isothermal amplification (LAMP)(13-16), recombinase polymerase amplification (RPA)(17-19) etc, showed a great convenience for point-of-care diagnosis, especially for resource-limited setting, but it lacks of detection throughput and sensitivity in field diagnosis, especially appearance of false positive or negative results. CRISPR based diagnostic platform (CRISPR-Dx) as a new emerging nucleic acid detection technology used for point-of-care diagnosis, such as Cas12a mediated plasmodium detection assay(20), showed great sensitivity and specificity, but it requires expensive Cas protein from commercial corporation and it is difficult to achieve multiple objects detection in a single closed tube.

Herein, we proposed a Universal two-dimensional labelled Probe-mediated Melting Curve Analysis (UP-MCA) assay based on multiplex PCR within four fluorescence channels at real-time PCR instrument for malaria genotyping. It is a rapid, sensitive, specific, low cost and high throughput detection strategy for five plasmodium species, including *Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae, Plasmodium ovale, and Plasmodium knowlesi*, with human ribonuclease P (RNase P) gene as the internal control in state of one-pot and closed tube following introduction
of genome extract. Moreover, the assay was validated by detection of clinical malaria samples and showed as a good alternative tool for clinical malaria diagnosis.

**Materials and Method**

*Collection and genome extraction for clinical samples*

Clinical blood samples were collected from Mengchao Hepatobiliary Hospital of Fujian Medical University from July 2016 to March 2020 with one sample came from one person, including patients with signs and symptoms of, such as fever, fatigue etc. which is similar to malaria. And genome extraction of 200 microliters whole blood for these samples were prepared by Ex-DNA whole blood extraction kit using automated nucleic acid extraction equipment (NP968-C, Xi’an Tianlong Science and Technology Co., Ltd, China) and 80 microliters nucleic acid extract were left over and measured by Nanodrop 2000 (Thermo Fisher Scientific, USA). They were stored at -20 °C until used.

*Principle of species-specific plasmodium detection assay*

Although real-time PCR based on sequence specific probe shows higher sensitivity and specificity than that using saturated or unsaturated dye, such as SYBR Green or Eva Green, the amount of detected objects are limited because of limited fluorescent channels of real-time PCR equipment. So, in order to achieve more objects detection in one reaction, we proposed that universal two-dimensional labelled probe-mediated melting curve analysis based on multiplex PCR (UP-MCA) assay for reliable detection of five common species-specific plasmodium in one-pot reaction. This method combines multiplex PCR with melting curve analysis, which is mediated by universal fluorescent probe corresponding to specific fluorescent channel and annealing temperature (Tm) produced for hybridization with homology tag that carried in plasmodium species-specific primer. Its process involves that polymerase mediated asymmetric amplification using target specific primers for tag mark of specific amplicon and fluorescent detection depending on hybridization between
homology tag and non-target sequence dependent universal fluorescent probe. Different Tm values brought out by variable degrees of hybridization analyzed by melting curve analysis are used for detection of specific plasmodium candidates in addition to difference of fluorescent channel (Figure 1). According to the previous research, this two dimensional label method can achieve detection of dozens of objects in one reaction under different fluorescence and elaborate Tm value representing detailed detection object (21).

**Design and synthesis of plasmodium species-specific primers and universal probe**

Initially, the amplification targets for P. falciparum, P. vivax, P. malariae, P. ovale and P. knowlesi based on previous studies (10, 11, 20, 22-24) and available gene sequences in GenBank were analyzed. Following that, nuclear small subunit (SSU) rRNA gene was confirmed as plasmodium detection target and used for the design of plasmodium species-specific primers as a result of the availability of its sufficient copies and conservative and species-specific sequences for plasmodium detection. Hence, we further blasted the sequences of SSU rRNA gene in P. falciparum (GenBank accession no. M19172), P. vivax (GenBank accession no. X13926), P. ovale (GenBank accession no. L48987), P. malariae (GenBank accession no. M54897), and P. knowlesi (GenBank accession no. AY327550) using the software ClustalX and selected one sequence region existing great difference, also existing high homology for plasmodium genus for the availability of number of primers reduction. Following that, homology and difference sequences were selected for the design of plasmodium UP-MCA assay of abundant forward primer (AF primer) and limiting reverse primer (LR primer), respectively. All primers and fluorescent probes were synthesized from Sunya Biotech (Fuzhou) Co., Ltd and Sangon Biotech (Shanghai) Co., Ltd. And DNA plasmid standards of different plasmodium species-specific and conservative fragments of SSU rRNA gene and fragments of human RNaseP gene were constructed by General Biosystems (Anhui) Co. Ltd.

Universal fluorescent probes and tags for species-specific plasmodium detection were chosen from previous research (21). Furthermore, variable degrees of hybridization
between homology tag and universal fluorescent probe determine the detail Tm value resulted from their effective hybridization length and base pairing degree. So we inferred and verified that homologous tags of certain length used for real hybridization with universal probe can also result in different Tm values corresponding to different candidate.

Establishment of Universal two-dimensional labelled probe-mediated melt curve analysis (UP-MCA) for species-specific plasmodium detection assay

DNA standards of SSU rRNA gene from species-specific plasmodium were prepared before establishment of detection assay (Table. S1). In order to achieve better performance of plasmodium detection, optimizations were implemented by the assay of polymerase enzymes (Taq DNA Polymerase, TaKaRa Taq HS, Vent® (exo-) DNA Polymerase, Klenow Fragment (3’→5’exo-), all of initial concentration are 5 U/μl), buffers (Taq buffer, Taq HS buffer, buffer A, buffer M, buffer 6 and PCR buffer, initial concentrations of all are 10×), temperature (54~66 °C) and concentration of Mg²⁺ (3~6 mM) and primers. Furthermore, Extreme Thermostable Single-Stranded DNA Binding Protein (ET SSB) is a single-stranded DNA binding protein used for stabilization of ssDNA structure and improvement of the processivity of DNA polymerase following that increasing the yield and specificity of PCR. Therefore, we also took ET SSB into consideration for assay optimization.

For single-plex assay, the reaction volume of twenty-five microliter including 1×Taq HS buffer, 1.5 U TaKaRa Taq HS (5 U/μl), 4 mM MgCl₂, 200 μM dNTP (A/G/C/T), 0.2 μM universal fluorescence probe, 0.8 μM abundant forward primer, 0.04 μM limiting reverse primer with homologous tag, 2 μL template. The assay was performed at the standard two-step PCR protocol with initial denaturation at 95°C for 3 min followed by 50 cycles of denaturation at 95°C for 15 s, annealing / extension at 60 °C for 45 s, then addition of melting curve analysis from 35 °C to 85 °C before sufficient denaturation at 95°C for 1 min and hybridization at 30°C for 2 min. Parameter replacement of annealing / extension at 64 °C and addition of 4 ng/uL ET SSB were used for multiplex species-specific plasmodium detection assay. The
different channel fluorescence (FAM or HEX or FAM and HEX) can be only
collected during the process of melting curve analysis, not for amplification process.
The reaction was occurred by the fluorescence PCR equipment (Applied Biosystems
7500 Real-Time PCR System in this study; Thermo Fisher Scientific).
As defined herein, the determination of detected result was taken by the fluorescence
channel and preset Tm value. And positive result of sample for one subject was
refined as the $-d(RFU)/dT$ value of melt peak height was 1.5 times more than that of
negative control which RNase-free water or non-plasmodium DNA or RNA serve as
reaction template.

**Performance evaluation of UP-MCA assay (including sensitivity, specificity,
selectivity and clinical performance) for plasmodium detection**

For evaluation of the sensitivity of UP-MCA for species-specific plasmodium assay,
the preparation of reaction template was used by a series of gradient dilution
concentration of various plasmodium plasmids from $10^5$ copies / μL to $10^1$ copies / μL.
Various concentrations of different plasmodium plasmids served as template were run
at least in triplex wells. The selection of some pathogens of similar clinical symptoms
or blood-borne diseases, including Babesia, Borrelia burgdorferi, Chikungunya virus,
human immunodeficiency virus, Hepatitis B virus, Hepatitis C virus and Novel
coronavirus (2019) was applied for the assessment of the specificity of this UP-MCA
assay. For examination of the selection and distinction ability of species-specific
plasmodium detection assay, two neighboring objects at the same fluorescence
channel, Plasmodium falciparum and Plasmodium vivax, were taken into observation
of accurate detection of plasmodium species. Furthermore, negative control of
RNase-free water or non-plasmodium genome served as template for plasmodium
assay was taken for above three tests.

Practically, the performance evaluation of species-specific plasmodium detection
assay was carried out by multiplex UP-MCA fluorescence system using a total of 184
clinical blood samples mentioned above, including 164 microscopy-positive of
malaria and 20 microscopy-negative of blood-borne diseases with similar signs and
symptoms consistent with malaria. Before they tested, all microscopy results of clinical blood samples were blind for the tester of the assay. And various plasmid standards of objects containing internal control human RNaseP gene under the concentration of 100 copies/μL were served as positive control for the assay and the RNase-free water was used as negative control.

Data analysis

As the analysis of the performance of our UP-MCA assay, we considered microscopy as the gold standard analysis. The discordance of result was considered for samples of which UP-MCA assay detection results did not agree with microscopy results. Discordant samples were retested with alternative multiplex qPCR method based on Taqman probe recommended by World Health Organization(11). Then we considered samples with identical results as true-positive PCR results, since assigning a species is not always possible with microscopy. Moreover, all data were analyzed with GraphPad Prism software. Each experiment was repeated at least three duplicates for each sample.

Results

**Principle of UP-MCA detection assay for species-specific plasmodium**

UP-MCA detection assay is a method that uses asymmetric PCR to achieve the enrichment of two-dimensional labelled products, and combines probe mediated melting curve analysis technology to achieve specific detection of targets with non-target sequence dependent universal fluorescent probes. With regards to asymmetric PCR and melting curve analysis, the difference in the proportion of forward and reverse primers will be introduced into amplification and two-dimensional label should be integrated into amplicon, respectively. Moreover, to further simplify primer design and minify optimization of assay for specificity improvement, we adopted asymmetric PCR of plasmodium genus forward primer which serves as abundant primer, and plasmodium specie-specific reverse primer with homologous tag at the 5’ end representing specific Tm value produced by
hybridization with universal probe, which serves as limiting primer for multiplex
UP-MCA plasmodium detection (Table 1). These primers were based on target SSU
rRNA gene of plasmodium, which its copy number range from 4 to 8 and known to be
highly conserved regions suitable for molecular detection of human malaria parasites.
This method was also helpful to improve the stability of Tm value of melting curve
analysis and avoid the false negative caused by low hybridization between amplicons
and specific probes, such as Taqman probe, that are susceptible to mutations of target.
For universal fluorescent probe, we proved different kinds of probe quenching method,
such as base-quenching and self-quenching, can be used for UP-MCA analysis
(Figure 2A). Furthermore, we speculated and also confirmed that different effective
lengths of tag could be used for hybridization with probe which was inspired by
different Tm value produced by variable degrees of hybridization (via mutations)
between homologous tag and fluorescent probe (Figure 2B and Table 1). It seems to
be easy to design probes and tags which can simplify a large number of optimization
of predicted Tm value via hybrid simulation and synthesis of primer with tag for be
tried out. This will help to homogenize temperature range of melting curve analysis
and improve detection throughput within a limited temperature range.

Optimization of UP-MCA assay for species-specific plasmodium detection
To improve reaction efficiency, the possible influencing factors were optimized via
different enzymes, buffers, reaction temperature and concentration of Mg²⁺. We found
that hot-start enzyme of TaqHS and the corresponding buffer or buffer M were the
main influencing factors for species-specific plasmodium UP-MCA assay (Figure 3),
and the assay obtained higher signal to noise (also difference of melt peak height
between positive and negative control) at the parameter of 4 mM Mg²⁺ and 63 °C
annealing temperature (Figure S1 A and B) using the same concentration of target for
multiplex plasmodium detection. Interestingly, it seems that ET SSB served as an
enhancer of specificity of amplification was not functioned in the multiplex
species-specific plasmodium UP-MCA assay (Figure S1 C).
Performance of plasmodium UP-MCA detection assay (including sensitivity, specificity, selectivity)

To evaluate the sensitivity of the UP-MCA plasmodium detection assay, a series of gradient concentration of diluted plasmids of plasmodium species and human gene (RNase P, internal control) as reaction template were tested. The results showed that the melt peak height representing negative derivative of fluorescence value with temperature (-d(RFU)/dT) of each object decreases gradually with the decrease of concentration of plasmids, and the LOD for each object was 10 copies / μL (in addition to Pm, 100 copies / μL) (Figure.4A) that nearly access to within the LOD required by WHO.

To assess the specificity of the UP-MCA plasmodium detection assay, genome of samples from a panel of homologous pathogens and that of blood-borne diseases having similar clinical symptoms or signs to malaria were tested. Three duplicates were performed, and 100 copies of species-specific plasmodium standards were used as templates of positive control for each reaction. Consequently, there were no positive results from the tested pathogens except for the DNA standards of species-specific plasmodium (Figure.4B), indicating that the high specificity of species-specific plasmodium UP-MCA assay for detecting plasmodium of detailed genotype.

To investigate the selectivity of the UP-MCA plasmodium detection assay, *Plasmodium falciparum* and its adjacent *Plasmodium vivax* at the same fluorescent channel were selected to test the accuracy of the UP-MCA detection assay. Specifically, different ratios of Pf and Pv plasmid standards under the 100 copies concentration range from 0:100, 1:99, 3:97, 5:95, 10:90, 20:80, 50:50, 80:20, 90:10, 95:5, 97:3, 99:1, 100:0 were prepared and performed by the multiplex plasmodium detection assay. The result showed that the assay exactly detect different kinds of dosage ratios of adjacent detected objects from the same fluorescence channel (Figure.4C). The assay method has excellent discrimination ability of detection.

Results of clinical sample via UP-MCA detection assay for plasmodium
To evaluate the clinical diagnosis performance of the plasmodium UP-MCA detection assay, 184 patients samples (164 positive-result and 20 negative-result for plasmodium microscopy), which had been confirmed by microscopy served as the gold standard method for malaria, were tested by detector covered microscopical results above. There were 164 plasmodium-positive samples and 20 plasmodium-negative samples detecting by the plasmodium UP-MCA assay which were all consistent to the results of plasmodium microscopy. Compared with the gold standard detection method, the plasmodium UP-MCA assay showed the sensitivity and specificity of both 100% (Table 2).

Discussion

PCR, as one of the most widely used molecular biology detection methods, has the great advantages of high sensitivity and specificity, simplicity and rapidity, and low cost, especially for real-time quantitative PCR. It has been used in many fields including pathogen detection, tumor marker detection, and genetic identification and so on. We demonstrated universal two-dimensional labelled probe-mediated melting curve analysis (UP-MCA) assay based on multiplex PCR for malaria that are sensitive and specific for detection of the 5 major plasmodium species as well as the human RNase P gene as an internal reference control with the employment of two fluorescence channel. The multiplex plasmodium PCR assay can be performed rapidly (nearly 3 hours, including 1 hour for genome extraction and 2 hours for amplification and detection) in a single closed tube, and the 384-well or 96-well format both achieve high detection throughput, which is required for large clinical sample detection and epidemiologic studies of imported malaria.

We rigorously investigated the plasmodium target gene based on its inherent characteristics (including conservation, specificity and copy number etc.) and previous published studies. The nuclear small subunit (SSU) rRNA gene of plasmodium harboring four to eight copy numbers was carefully defined as target gene for the reason that not only that is known to be highly conserved regions suitable for plasmodium-genus primers selection, but also its existence of plasmodium-species
region for specific primers design. Less optimization can be conducted by one abundant primer selected from conservative region and numbers of limiting primers designed from species-specific region for multiplex and asymmetric PCR detection for plasmodium. Furthermore, many optimizations for detection efficiency improvement were rigorously carried out, including main factors of specific primers, enzymes and best matching buffer etc.

For the UP-MCA assay, engineered fluorescent probes were not directly specific for target sequence, but it was dependent on species-specific limiting primer used in asymmetric PCR resulting in abundant single-strand DNA products with specific tag for special hybridization. It is helpful to improve the resistance of mutations or SNP existed in probe hybridization region and theoretically increase sensitivity of the plasmodium detection assay. Moreover, in addition to mutation existing in homologous tag, our experiment showed different effect hybridization length between tag and fluorescent probe also can be applied in two-dimensional label design strategies for universal probe. It was great advantage for difficulty reduction of two-dimensional label design and throughput improvement of detection target following homogenization of melting temperature, unfortunately lacking of further more detection objects in one-pot to be validated.

Limitations were also demonstrated in the plasmodium UP-MCA detection assay. Firstly, there should be more targets to be validated for detection throughput improvement used in plasmodium UP-MCA assay, and less detection objects and numbers of primers may be the reason of ET SSB seldom seems to be functioned. But, in other words, primers designed and used in the assay were adequately specific for species-specific plasmodium. Secondly, the UP-MCA assay was one of half-quantitative multiplex method that could not accurately achieve to quantitative plasmodium species. Furthermore, more clinical samples collected from multicenter should be incorporated into the assay for clinical performance validation.

In summary, we developed one plasmodium species-specific detection assay for greatly enhancing sensitivity and specificity that was important for import malaria derived from regions or cities of frequent communications for economy or population
emigration and immigration. It can be rapidly and accurately genotype 5 plasmodium species and great helpful to increase the ability of eliminating imported malaria.

In summary, the developed plasmodium UP-MCA assay exhibited excellent sensitivity, specificity and selectivity for plasmodium species-specific detection. It is helpful to rapid and sensitive genotyping of 5 species-specific plasmodiums in a single closed tube under malaria control plan accordingly proposed by World Health Organization.

**Figure Legends**

**Figure S1** Optimizations of plasmodium UP-MCA assay. Detection performance of plasmodium UP-MCA assay at different annealing temperature (A). The efficiency of plasmodium UP-MCA assay at different concentration of Mg ion (3 mM, 4 mM, 5 mM, 6 mM) (B). The amplification efficiency for plasmodium UP-MCA detection assay at different concentration of ET SSB (C).
