Abstract

Combinations of common drugs may, when taken together, have unexpected effects on diseases like cancer. It is not feasible to test for all combination drug effects in clinical trials, but in the real world, drugs are frequently taken in combination. Then, there may be undiscovered effects protecting users of drug combinations from cancer—or increasing their risk. By analyzing health claims data containing numerous people exposed to drug combinations, we have an opportunity to evaluate the association of drug combinations with cancer risk. Discovering these effects can not only contribute to prevention of cancer, but also suggest new clinical uses for drug combinations to prevent or treat cancer. Here we describe new methods for discovery of drug combination effects on cancer. Our approach emulates a randomized trial where one arm would have been assigned to take a drug alone, while the other arm takes the drug together with a second drug. Because discovery of associations from observational data is prone to spurious results due to confounding, we develop a number of strategies to distinguish confounding from biomedically relevant findings.

Introduction

Late onset chronic diseases are responsible for a bulk of deaths, with cancer ranking as the second leading cause of death. Despite intensive research, we have not identified effective ways of preventing most cases, and new treatments are urgently needed. To address this problem, one approach is to investigate what common exposures could be associated with disease risk. Among people over 40 years old, one third use two or more drugs, and 20% use more than five medications. We propose that combinations of common medications could influence cancer risk. These effects are unlikely to have been uncovered in randomized trials, but examples exist. While estrogen replacement as a treatment for menopause is not linked to adverse cancer outcomes, combining estrogen with progesterone appeared to increase risk of breast cancer over a three year follow-up period. Statins, prescribed for high cholesterol, have been linked to reduced incidence of multiple cancer types in epidemiological studies, and they are in trials for cancer therapy. Trials have investigated anti-cancer effects of statins combined with celecoxib (anti-inflammatory) and metformin (a diabetic drug). Therefore, common drugs may both positively and negatively impact disease.
As tens of thousands of common drug combinations could be tested for any of a dozen types of common cancer, these effects are unlikely to be discovered through experimental trials. Outside of the setting of clinical trials, one approach to discovering such drug effects is analysis of observational data. Using such health data, we can follow health outcomes in people exposed to the drug combination. Although reusing existing data is fast, cheap, and allows systematic discovery, new methods are needed to find drug combination effects. Unlike experimental data, observational data is subject to confounding: people are prescribed drugs based on their health, and some health conditions incur increased risk of cancer. For instance, smoking increases lung cancer risk, meaning that people who take smoking cessation drugs are likely at increased risk of lung cancer. Without accounting for such variation in health, the drugs and drug combinations most associated with cancer would be dominated by such spurious associations.

The typical approach to discovering a biomedically relevant association from observational data is to attempt to emulate a randomized trial that could have investigated the same question. Two study cohorts, consisting of users or non-users of a drug are "enrolled", and then the analysis compares their outcomes, adjusting for confounders of the association. While we do not know of other drug combination-wide studies, we have reviewed previous drug-wide association studies of cancer (single drug, not combinations)⁴⁻⁷. Because of their systematic nature, these studies make some simplifying assumptions. Particularly, they adjust for a limited set of confounders such as age, sex and a summary comorbidity index. It is not clear if these measures are adequate. One tactic, called "empirical calibration" compares the effect of a drug on outcomes of interest against its association with selected "negative control" outcomes⁸⁻⁹. For instance, we expect most common drugs do not affect risk of ingrown nails. This systematic approach allows us to summarize the distribution of effect estimates on a range of outcomes. The authors suggest that we can estimate, and thus remove, the bias by assuming all effect estimates are centered around the overall bias. One weakness of this assumption is that bias is often specific to the particular pair of exposure and outcome. For instance, people taking smoking cessation drugs are at risk of lung cancer, but not breast cancer. As well, randomly selected negative controls may not suffer the same bias; we expect no confounding effect associating smoking cessation agents with ingrown nail.

Therefore, here we develop new methods for drug combination-wide association studies. Our aim is a systematic discovery of drug combinations that, like other drug-wide methods, allows unprejudiced investigation of any observable drug combination. We accept that due to the nature of observational data, our results must be replicated and verified by future experimental studies. But, we make extensive efforts to identify the effect of confounding, and we use a number of sensitivity analysis to pinpoint associations that are most robustly supported. We expect both our methods and the identified drug combination associations can provide advances toward clinically relevant insights from observational data.
Results

Observational data to emulate a randomized trial of drug combinations

In order to set up our approach, we first design a randomized trial that would test the association of any arbitrary combination of drugs with a common cancer outcome. Our design is inspired by the case control study. We make a design to estimate the effect of a combination of the arbitrary pair of drugs A and B. Our design enrolls new users of some drug A who have never before taken either drug A or B, and with no history of cancer. Then, our hypothetical trial would randomly assign some people to additionally take drug B (Fig 1A). Finally, we would follow these two groups to observe incidence of cancer. Analyses of the results could follow all people randomized, called an intention-to-treat analysis. An alternative analysis could censor follow-up time for those who discontinued use of drug A, known as a per-protocol analysis.

To emulate such a trial, we use a set of health claims data from Truven MarketScan (now IBM), containing 150 million drug users. Our study uses data with coded diagnoses, prescriptions, and procedures, alongside basic demographic characteristics, over a twelve year span from 2003 to 2015. We observe 9,502 drug combinations with a median of 4,979 combination users per drug pair (Fig 1B), and with a median of 20 exposed people who eventually develop cancer across all cancer types (Fig 1C). To summarize, we perform this emulation of a randomized trial for 9,502 pairs of a drug A and B. For the rest of this manuscript, we refer to the first drug as drug A, and the second drug as drug B. In theory, we might expect the same true effect if the order of the drugs were reversed, but in practice sample size limitations mean we rarely observe both orders.

Approach to emulating the randomized trial

We divide our main design into three steps, analogous to steps of a randomized trial: 1) enrollment (creation of our cohorts); 2) randomization (adjusting for time-varying confounding); and 3) analysis of outcomes and estimation of effects.

In the enrollment step, as mentioned, we compile all new users of drug A, who have never taken drug B or had the outcomes of interest. While in the randomized setting, some subset would be immediately assigned to take the combination of drugs A and B, in the observational setting, some people will start drug B immediately, while others might start drug B later. While we could only compare those who start drug B immediately after drug A against those who

Figure 1. A Hypothetical randomized trial of drug combinations. B. Total numbers of people exposed to a drug pair, across 9,502 drug pairs. C. Number of cancer cases per drug pair, aggregated across all common cancers.
take drug A alone, this choice would drastically reduce our data size. In order to capture all person-time under joint exposure of the drug combination, we follow the approach of emulating a sequence of randomized trials\textsuperscript{10,11}. This tactic divides follow-up time after initiation of drug A for each person into arbitrary but reasonable windows (we choose 3 or 6 month windows). Each time window defines a trial in the sequence of trials: a person who has not initiated drug B yet at follow-up time window \( w \) remains eligible to "enroll" in a trial that starts at that time window (Figure 2). Therefore, we are able to include all joint users of drugs A and B in one of these trials. For instance, a person who started the drug combination in window 3 is in the treated group for trial 3, but is in the comparator group for windows 1 and 2. This person is not eligible to join trials starting after trial 3. We can easily account for this replicated data by indicating the repeated observations in our statistical analysis (see Methods).

![Figure 2](image_url)

**Figure 2.** Enrollment for trials. Medical history is represented along the horizontal axis. Follow-up time is divided into 3 windows. The top three people are eventually exposed to the combination of drugs A and B (blue pill), while the bottom two people remain in the comparator group (drug A alone). **A.** Representation of the expansion of person-time for these five people into a sequence of randomized trials. Person 1 is unexposed at time window 1 (trial 1), and thus is in the comparator group, but still eligible to participate in trial 2. At trial 2 they receive the combination, and thus are assigned to the joint-exposure group in trial 2, and they are not eligible to participate in trial 3.

In the randomization step, we emulate randomization by adjusting for time varying confounding. It is crucial to not only adjust for disparities between the treated and comparator groups at baseline initiation of drug A. This is because changes in health over time can
influence which people are prescribed drug B (Figure 3). For instance, onset of menopause ("Health at time 1" in Figure 3) might prompt prescription of drugs to treat the symptoms, and menopause also increases risk of breast cancer. Therefore, if we do not adjust for time-varying confounding we would find a spurious association between menopause-related drugs and breast cancer. Previous drug-wide methods that analyze use of single drugs only have not required time-varying analysis, and these methods have adjusted only for selected confounders. Instead, we consider that all medical history before time window \( w \) could include possible confounders. Because of the time-specific nature of medical data, colliders\(^{12,12} \) are unlikely: this would require both the treatment and the exposure to affect some variable that occurs before either of them. While errors in the medical record induce some cases of reverse causality, we describe measures taken to guard against this issue later.

To model confounding, we calculate probability of initiating drug B, based on both time window-specific and overall medical history. Confounding also can influence whether someone discontinues drug A, an issue that also arises in analysis of the data from a randomized trial. In a per-protocol analysis of randomized trials, person-time is censored after discontinuation of drug A. In order to best capture the effect of exposure to drug combinations, we also censor person-time after discontinuation of drug A. To account for confounding impacting censoring, we also model probability of discontinuation in the same way as we model initiation of drug B.

Finally, we obtain time to cancer outcome using a survival analysis. The probabilities calculated in the randomization step are used as weights to remove the confounding-related association between drug and outcome in a marginal structural model\(^{13} \). In this manner, we can estimate the association between each drug combination and each common cancer, for those where enough cases are observed.

**Drug-wide studies may be influenced by a wide range of confounders**

Our analysis yields estimates for 9,502 drug combinations, for a median of 22 cancers where more than 100 people in the cohort study were diagnosed with that type of cancer. As mentioned, previous drug-wide studies typically account for only a handful of confounders. We investigate the possible effects of considering a narrow range of confounders. In Figure 4, we compare the effect estimates that consider no confounders (unweighted); those derived from cohort studies that only adjust for age, sex, year, and Charlson comorbidity index (minimal confounding control); and our method of including a wide range of possible confounders (weighted estimates). We find that globally, the effect estimates are greatly reduced. Because this is a general effect, across many drug combinations and cancer outcomes, we conclude that this is likely to be due to a number of assorted confounding effects, rather than due to widespread effects of drug combinations of cancer. This suggests that other drug-wide...
studies would benefit from considering a wide range of confounders. However, the results also suggest that there is likely substantial remaining confounding. The ability to support such conclusions is a key advantage of taking a systematic drug (combination)-wide approach to discovery.

Initial results of the drug-combination wide scan and remaining confounding

Across around 200,000 resulting effect estimates, we investigate selected examples to assess the nature of the remaining confounding. Among drugs most associated increased risk of cancer, we find two obvious patterns. First, drugs that are used in the treatment of cancer appear associated with rates of multiple types of cancer. For example, fentanyl, morphine, and other pain treatments, as well as anti-nausea medications such as prochlorzepine or ondansetron appear co-prescribed in cancer cases. This is likely due to incompleteness of the medical record: these people are overwhelmingly likely to be under treatment for cancer. Then, this is a case of reverse causality, where the medications are a result of the diagnosis, rather than the other way around. Reverse causality is usually associated with many common cancers, as in Figure 5A, as many cancers involve surgery, chemotherapy, and drugs to manage the symptoms and complications of these procedures. We later present a simple heuristic to sort these cases.

The second pattern includes likely cases of confounding, which is usually specific to one type of cancer. For instance, kidney disease impacts glaucoma, and we find that people taking a combination of two glaucoma treatments (latanaprost and travaprost), as compared to those who take only latanoprost, are at higher risk of kidney cancer (Figure 5B). This is overwhelmingly likely to be due to the confounding effect of kidney disease on risk of both kidney cancer, and glaucoma (and thus these drugs). Note that this combination is specifically associated with kidney cancer, which is logical due to the specific confounding effect of kidney disease. Such examples indicate remaining confounding, a separate issue from reverse causality. Again, our systematic exposure-wide assessment enables identification of this issue.

Because the presence of confounding in observational studies is well known, approaches like the Hill criteria seek to distinguish epidemiologic signals with strongest evidence of biomedically relevant effects. We first focus on two criteria: consistency and specificity.
Consistency: First, we examine the consistency among results that we would expect to be consistent with each other. Some previous findings of drugs impacting cancer, like statins, appear to impact multiple cancer types. Our examples of confounding (rather than reverse causality), on the other hand, are specific to a single cancer. Therefore, our current analysis seeks drug effects that are consistent across multiple common cancer types. As well, we consider consistency among drugs sharing an active ingredient as another form of evidence.

Taking inspiration from the consistency heuristic, we implement an analytical approach to integrate the results of multiple cohort studies and distinguish the strongest signals from confounding. Because of the size of the data and the even larger size of the data when expanded into a sequence of windows of person-time, we split up any large cohort studies into replicate cohort studies containing disjoint study populations. We integrate these multiple effect estimates in a new Bayesian hierarchical model, to estimate the per-combination effects on any cancer (Figure 6). The first level of the hierarchy assumes that the replicate cohort study effects of the drug combination on each common cancer are centered around the true per-cancer effect of that combination. Then, at the next level, our model specifies that effects of the combination on a particular cancer type are centered around the overall pan-cancer effect of the drug comb
In a slightly different model, we estimate the effects for a combination of drug A and all members of the set of drugs B that share some particular active ingredient. This model only differs from the previous model in that it has one extra layer in the hierarchy: we assume that the per-cancer effects for the drug are drawn from the overall effect of that ingredient class on that type of cancer. The effect estimates yielded by the Cox regression comprise the data input to the model. After fitting the model to the effect estimates, we obtain the posterior distribution of the overall effect of the combination on cancer. We classify protective drugs as those where the upper 1% posterior interval is less than zero, and predisposing drugs as those where the bottom 1% is greater than zero.

**Specificity:** Second, another criterion examines whether the associations are specific to the outcome of interest. We could imagine that people in poorer health simply take more medications; many indicators of poor health, such as sedentary lifestyle, increase overall cancer risk. But, we may expect in that case that these people may have increased risk of other non-cancer diseases. Therefore, the association would not be specific to cancer but would correspond to general sickliness. We create a set of negative control outcomes, matching each common cancer with a non-cancer outcome with a roughly similar incidence rate in our study population (Figure 7A). These outcomes are chosen to span a wide range of body systems. We apply the same hierarchical model to our negative control outcomes, which allows us to identify drug combinations that are generally associated with illness.

**Detecting reverse causality:** We found many examples of reverse causality, similar to the one illustrated in Figure 5A. As mentioned, we expect that these are due to erroneous missing information about a cancer diagnosis, where eventually the diagnosis is recorded in the coded data, but only after some amount of treatment. It is reasonable to assume that when cancer in fact causes the treatment, the diagnosis of cancer will occur close in time to the treatment. We develop two tests to detect these cases. First, we test among cancer cases,
whether the duration of time between the trial start date and date of cancer diagnosis is shorter among those treated with the combination (Fig 7B). Second, we test whether this temporal relationship is stronger for cancer types more strongly associated with the drug combination. In this manner, we can exclude the obvious cases of reverse causality.

Sensitivity analyses to strengthen findings

After the previous series of tests, we are left with only a few drug-combination wide associations. We further subject these signals to a set of sensitivity analysis. These test whether the results are sensitive to some of the design decisions we made. We re-run the same drug wide association study for the candidate signals, twice, each with two different sets of assumptions. For each, we perform the consistency analysis to assess whether the drug pair impacts all-cancer risk.

First, we change the window width used for defining trial start periods. While our primary design used 6 month windows, we create a secondary analysis that uses 3 month windows to define trial start periods. Note that this creates more follow-up periods, and results in a larger person-time matrix. Our second sensitivity analysis tests the effect of varying the definition of drug combination. While our main analysis censored person-time when the person stopped taking drug A, this results in a very limited follow-up time, where most people are followed for no more than a year. We expect this can only allow us to detect smaller drug effects. Removing this requirement, we can follow time after exposure for an average of 3.25 years, which is as long as people are followed for cancer outcomes in some randomized trials. Removing the censoring greatly increases the number of cancers we can observe in follow up, but it also increases the size of our expanded person-time matrix, necessitating smaller replicate cohort studies.

Our final sensitivity analysis assesses the association of amount of drug B dispensed with cancer incidence. We find
empirically that most drugs have a few common amounts dispensed, and we simply categorize users as in the "low" amount group or the "high" group. For instance, for fenofibrate users two main amounts dominate. Because the number of people exposed to a drug combination and later getting cancer is rather low, we do not further categorize drug amounts. We consider the signal has passed this test if 1) both categories are significant and 2) the effect size is stronger for the high group than for the low group.

Combining the sensitivity analyses with the reverse causality test, we narrow down our signals to the final associations. Our final results are presented in Table 1 and Table 2 (see end). We find 50 single drug pairs are associated with either an elevated or a reduced rate of cancer. Among these, many can be further excluded from a cancer effect by the negative control test. Further, by combining signals across drugs in ingredient categories, we can prioritize drug combinations with a consistent effect in the ingredient class. Among our protective findings, only the combination of omega-3 fatty acids plus fenofibrate was able to be tested as an ingredient class (where fenofibrate is an ingredient of both fenofibric acid and fenofibrate). The ingredient class also was associated with reduced risk of cancer. As well, the sensitivity analysis for amount of medication dispensed showed stronger protective effects for the high amount versus the lower amount (average log hazard ratio of -2.9 for the high amount, versus -1.6 for the low amount).

Discussion

We have described a systematic method to perform a drug combination-wide association study across all cancer types. While further studies are needed, one interesting finding is that a combination of Omega 3 acids (fish oil) with fenofibrate may be protective of cancer. Our negative control analysis indicates that this is not merely an effect of increased health consciousness but is specific to cancers. Our analysis of amount dispensed and other sensitivity analysis further supports the results over a 3 year follow up period. This pair of drugs both impact circulating lipid levels. Circulating lipids are thought to impact cancer development via the Warburg effect. Therefore a biomedically relevant effect is plausible.

Our analysis has a number of limitations. Foremost, our results display evidence of remaining confounding. We previously showed that the propensity score is not able to model many important types of confounding. This is because the medical record is incomplete. Many unpredictable factors can influence drug prescription, ranging from various comorbidities in medical history, to the patient's gender, ethnicity, and geographical location. Therefore, future work must improve upon the propensity score and enable better modeling of confounding. Our results can provide a starting point for these efforts by providing a large set of cases of real-world confounding. A second limitation of our work is the limited follow-up time available for observing drug combination effects. In our analysis with no censoring, we have 3.25 years of follow-up time available. This is short, but it is in line with some previously discovered combination drug effects.

Our unique approach has a number of strengths. First, this work represents, to our knowledge, the first application of marginal structural models for discovery of drug combinations impacting health outcomes. While marginal structural models have been used to describe effects of time-varying treatment, our unique design allows us to expand on these methods to
describe the time-varying effect of adding a second drug on top of treatment with an initial drug. Another unique method is our hierarchical model for combining drug effect estimates on related diseases to create an overall summary of the effect on a disease category. While some other studies have combined drug effect estimates using a hierarchical model\cite{17}, this approach is the first to use hierarchical models to identify an estimate across multiple diseases that is more robust to many types of confounding.

A final and crucial strength of our design is its systematic nature. By performing a systematic analysis across all drug combinations, we are able to compare methods and discover their weaknesses. For instance, we showed that methods that only account for a few general confounders are quite vulnerable to bias. Our thorough consideration of sensitivity to our study design, and our attempts to quantify remaining confounding, increase confidence in our results. We expect that this approach an provide a basis for future work seeking to discover drug combination effects from health data.

Methods

Expansion of medical record into person time

We divide up follow-up time into windows of time since initiation of drug A. Our main analysis uses windows of 24 weeks, and a subsequent sensitivity analysis uses windows of 12 weeks. For each window, we obtain patients' time-specific data, including if they started drug B, and other medical history of that time, including incidence of cancer. As outlined in Figure 2, we expand person-time into repeated trials. Specifically, people are eligible for a trial as long as 1) they are still observed in the data set (and not censored, depending on the design) and 2) they have not yet taken drug B, and they have not yet had the outcome of interest (here, a specific cancer). In trial 1, the person's full time observed is the amount of time available for follow-up. For subsequent trials, follow-up time begins only after trial initiation. In Table 3, we illustrate the expansion into person-time for person i and person v from Figure 2. The shorter the windows, the more rows will be in this table. As well, the longer the follow-up time (which increases when no censoring is performed), the more rows will be in this table.

person i is not eligible for trials after trial 2 because they took the combination at trial 2
Modeling confounding

Taking the marginal structural model approach, we must model both time-varying confounding and baseline confounding. We implement this with a sparse high-dimensional regression.

\[ p(\text{treatment}_{t} | \text{health}_{t}, \text{baseline info}) \]

We include as variables in \text{health}_{t} and \text{baseline} all treatments and diagnoses. Baseline also includes sex and cubic spline variables to model the effect of age, calendar time, and the number of total diagnoses and treatments the person has as a measure of overall medical burden. Typically, our data has over 10,000 features, but we filter the features observed in fewer than 100 people. We fit the model using elastic net logistic regression using the scikit learn package, performing a grid search with cross-validation to choose values for the regularization parameter and the l1-ratio. For each model, we perform the hyperparameter tuning separately. After regularization, typically only a few hundred features have a non-zero coefficient in the logistic regression model. Finally, we obtain the predicted probabilities from the model.

Marginal structural models and survival analysis

Using the predicted probabilities of treatment, we use marginal structural models to estimate the association with a cancer outcome. To this end, we use the predicted probabilities from our models to create treatment weights that estimate the probability of each person receiving the treatment sequence they in fact received, given their medical history. So, for person \( i \), this treatment sequence entails first being treated with drug A alone in time 1:

\[ p(\text{drug}_{0} = 0 | \text{health}_{0}, \text{baseline info}) \]

then being treated with the drug combination in time 2:

\[ p(\text{drug}_{1} = 1 | \text{health}_{1}, \text{baseline info}) \]

We obtain the probabilities at each time point from our model, and we multiply these to obtain the overall probability of the sequence of treatments up through person-time observation. Finally, we use the inverse of these probabilities to weight each time interval in follow-up time in the Cox regression using the R survival package\(^{13}\). This part of our analysis is similar to what has been implemented in other studies modeling a sequence of randomized trials with observational data\(^{10,11}\). As those previous publications proved that using the stabilized weights reduces extreme weights without adding bias, we use stabilized weights.

For designs where we censor person-time when the users stop taking drug A, we use the same procedure to adjust for time varying confounding of discontinuation for censoring. This is because time-varying confounding could cause censoring and could thus bias our results\(^{13}\).
Censoring

In our primary analysis, we censor people when they discontinue drug A. This is a design choice that allows us to estimate the effect specifically of simultaneous exposure to drugs A and B, rather than possibly sequential exposure. As mentioned immediately above, when censoring those who discontinue drug A, we must account for time-varying influences on censoring. We obtain the probabilities of censoring exactly in the same manner as obtaining the probabilities of initiation of drug B, simply modeling \( p(\text{discontinue drug A} = 0 | \text{health}_0, \text{baseline info}) \) using a high-dimensional sparse logistic regression model. Finally, we obtain the weights in the same manner described above. To weight each observation adjusting for confounding of both discontinuation of drug A and of treatment with drug B, we multiply the two weights together. While this makes the assumption that the two treatment decisions are independent, by performing the sensitivity analysis without censoring, we are able to assess whether that assumption impacts the results.

Hierarchical model

The hierarchical model shown in Figure 6 is presented in Appendix Model. The slightly simpler version without the ingredient layer is very similar. The model uses as input the log hazard ratios of the treatment effects estimated from the Cox regression model. These are assumed to have a normal distribution in the Wald test. Our model suggests that these estimates are samples derived from a normal distribution centered around a true effect estimate. We fit the model using Stan, and obtain the posterior distribution of the all-cancer effect from this model. We use the same model to obtain the effect estimate across all negative control outcomes, replacing the cancer estimates with the estimates of the effect of each drug combination on incidence of each negative control health condition.

Sensitivity analyses and other tests

We repeat our drug-wide analysis, but only testing drugs that have effects tested in our main analysis. For the first sensitivity analysis, we alter the size of the windows, and for the second sensitivity analysis, we do not censor when drug A is discontinued. Because, as mentioned above, both of these alterations can result in large increases in the size of the expanded person-time data set, we must reduce the number of drug A users included in some analyses.

To perform the reverse causality test, we gather data on time to cancer for the cancer most strongly associated with the drug combination. Considering only the people who eventually get that type of cancer, we use the rank-sum test to evaluate whether the time to cancer is significantly shorter for those taking the combination versus those in the single-drug group. These values are presented in Table 1 and 2, "reverse causality test" column.

To categorize combination users into those with "low" and "high" amount of drug, we obtain the two most common amounts prescribed. We set the cut point to be half way between those two amounts.
Table 1: Drug combinations associated with reduced risk of cancer. The negative control test is passed for those in yellow (no reduced risk of non-cancers)

**Table 2:** Drugs combinations associated with increased risk of cancer. The negative control test passes for those in yellow (no increased risk of non-cancer). But, most of these are cancer therapies and likely due to reverse causality.
