Abstract

Maternal autoantibodies can be transmitted diaplacentally, with potentially deleterious effects on neurodevelopment. Synapsin 1 (SYN1) is a neuronal protein that is important for synaptic communication and neuronal plasticity. While monoallelic loss of function (LoF) variants in the SYN1 gene result in X-linked intellectual disability (ID), learning disabilities, epilepsy, behavioral problems, and macrocephaly, the effect of SYN1 autoantibodies on neurodevelopment remains unclear. We recruited a clinical cohort of 208 mothers and their children with neurologic abnormalities and analyzed the role of maternal SYN1 autoantibodies. We identified seropositivity in 9.6% of mothers, and seropositivity was associated with an increased risk for ID and behavioral problems. Furthermore, children more frequently had epilepsy, macrocephaly, and developmental delay, in line with the SYN1 LoF phenotype. Whether SYN1 autoantibodies have a direct pathogenic effect on neurodevelopment or serve as biomarkers requires functional experiments.
Introduction

Synapsin 1 (SYN1) is a neuronal phosphoprotein encoded by the SYN1 gene and plays an important role in neurotransmitter release and neuronal plasticity (1, 2). Patients with loss of function (LoF) variants in the SYN1 gene have been associated with X-linked phenotypes consisting of epilepsy, learning difficulties, intellectual disability (ID), macrocephaly, behavioral problems, and autism-spectrum disorders (ASD) (MIM#300491, MIM#300115) (3-5).

In recent years, anti-neuronal autoantibodies have been increasingly described to cause target-specific autoimmune neurologic disorders, in some cases matching the clinical phenotypes of patient carrying genetic variants of these targets. For example, both patients with variants in GABA<sub>A</sub> receptor subunit genes and those with GABA<sub>A</sub> receptor autoantibodies display epilepsy as a common phenotype (6-8). Autoantibodies are usually regarded as those generated within an individual; however, they can also be transferred diaplacentally from mother to child (9). As the blood brain barrier is not yet fully matured, these autoantibodies of maternal origin can target the developing brain and thereby potentially affect neurodevelopment (9). There is increasing evidence that maternal immune activation through autoantibodies can influence the occurrence of neurodevelopmental disorders, such as ASD (9). In addition, multiple murine models have demonstrated the direct deleterious effect of various anti-neuronal autoantibodies in offspring through gestational transfer (10-13).

In previous studies, autoantibodies against SYN1 have been identified in patients with neurologic and psychiatric disorders (14, 15). We have recently shown that SYN1 autoantibodies in pregnant women are associated with abnormalities of fetal development including intrauterine growth retardation (Preprint) (16). However, their role in mothers of children with defined neurologic disorders has not been studied so
far. Thus, we assessed the prevalence of SYN1 autoantibodies in mothers of a
cohort of 208 pediatric patients with neurological disorders.

Material and Methods

Cell-based assay

Synapsin 1b (SYN1b) cell-based assay (CBA) was performed using human
embryonic kidney (HEK293T) cells which were transfected with human SYN1b.
Methanol-fixed cells were then incubated with sera diluted 1:300. IgG AF488-
antibody (Dianova, #109-545-003), commercial rabbit SYN1/SYN2 antibody
(Synaptic Systems, #106002) and anti-rabbit IgG AF594-antibody (Jackson IR, #111-
585-003) were used to detect IgG binding. Two independent investigators scored the
CBA using the following semi-quantitative score: 0, no binding; 1, unspecific signal
(‘background’); 2, positive (intensive binding). Sera were tested on control cells
overexpressing the NR1 subunit of the N-methyl-D-aspartate receptor (NMDAR),
contactin-associated protein 2 (Caspr2), and SYN1 CBA-positive sera also on
untransfected control HEK293T cells to exclude non-specific binding (14, 16).

Enzyme-linked immunosorbent assay

For the ELISA, 200 ng of recombinant rat Syn1-His-EGFP (17) was diluted in PBS
and incubated overnight at 4 °C in 96-well high-binding plates. Serum (1:200 diluted
in PBS containing 1% BSA, 0.05% Tween) was incubated for one hour at room
temperature, on which HRP-coupled anti-human IgG antibody (Dianova, #109-035-
003) was added for an additional hour. Ultra TMB substrate solution was added, and
reaction terminated after one minute with H₂SO₄. Absorbance at 450 nm was
measured and corrected with controls (mean of wells without serum and reference
absorbance at 630 nm).
Western blot

SDS-Page and Western blotting were performed as described using cortices from Syn1/2/3 triple knockout (TKO) mice and wild type (WT) mice (14). Sera of CBA with scores of 1-2 were diluted to 1:200 and used to incubate membranes. A rabbit polyclonal SYN1/2 antibody (#106002) was used as positive control and a mouse monoclonal antibody against glyceraldehyde-3-phosphate dehydrogenase (GAPDH, Merck Millipore, #MAB374) served as loading control.

Clinical data and statistical analysis

We studied a cohort of 208 mothers of pediatric patients with neurological disorders treated at the Center for Chronically Sick Children, Charité – Universitätsmedizin Berlin, Germany. Patient data were collected blinded to maternal antibody levels using a standardized data collection sheet. Statistical analysis was performed using R (RStudio version 4.2.1) and the packages crosstable, UpSetR, and psych. Descriptive statistics were performed to calculate percentages and frequencies. Differences in categorical variables are reported as odds ratio and 95% confidence interval. P values were calculated using the Chi-square test and Fisher's Exact Probability Test, as applicable. Test results with p<0.05 were considered statistically significant. The study was approved by the local ethics committee (approval no. #EA2/220/20).

Results

We screened sera for SYN1 autoantibodies in 208 mothers to assess the relationship with neurodevelopment in children. Due to the explorative approach, no exclusion criteria were set. Mothers gave birth at an average age of 30.93 ±5.81 years. Children (male n=134, 64.1%) were 6.6 ±4.14 years old at testing. Developmental delay in the domains speech (n=158, 75.7%) and motor skills (n=153, 73.1%) were
the most common findings. Furthermore, 135 patients had intellectual disability (64.4%), and 83 patients had epilepsy (39.9%) (Figure 1).

In a first step, the patients’ mothers were screened using the previously described CBA (14). We used a visual-scoring system for antibody binding in which scores of 2 were considered as positive (Figure 2A). Positive binding was identified in 20 mothers (9.6%). In 30 mothers, unspecific binding was detected while all others (n=158) showed no binding (Figure 2B). We further analyzed the sera of mothers with a SYN1 ELISA. Here, we found only a weak correlation between the CBA and ELISA results (r=0.29, Figure 2C). Possibly, these differing results can be explained by the binding of SYN1 autoantibodies to conformational epitopes that are not detected by ELISA. Therefore, we performed Western blots using the sera and cortex homogenates of wild-type and SynI/II/III triple knockout mice. We detected IgG binding to wild-type mouse brain homogenates in four of the 20 CBA-positive sera (Figure 2D). The other sera did not show immunoreactive bands at the expected molecular weight. These results point towards SYN1 IgG autoantibodies binding to linear SYN1 epitopes in only a small group, whereas autoantibodies against conformational synapsin epitopes predominate.

We further analyzed children of mothers with a positive CBA (Table 1). Most commonly the children had ID (n=18, 90%), speech delay (n=17, 85%), motor delay (n=17, 85%), and epilepsy (n=12, 60%). Seven patients had a developmental and epileptic encephalopathy (DEE). Cranial MRI was performed in 15 patients, with abnormalities detected in eight patients (53.3%, Table 1). Genetic testing was carried out in 13 patients, with variants (n=7) and microdeletions (n=1) identified in eight patients (61.5%). Of these seven variants, one was classified as pathogenic (14.3%), three as probably pathogenic (42.9%), and three as variants of unclear significance.
The four patients with IgG binding to wild-type mouse brain, showed no striking phenotypic differences to patients without binding (Table 1).

We next analyzed the clinical data based on the results of the CBA. While there was no association between CBA and age of mothers, age at birth or children’s age, we found an increased risk for specific phenotypes in patients of mothers with positive CBA. A positive CBA was a significant risk factor in their children for the presence of ID (OR: 5.46 [95% CI: 1.52 - 35.01], p = .0134) and behavioral problems (2.71 [1.07 - 7.23], p = .0328). Furthermore, patients showed a tendency for the presence of macrocephaly (3.11 [0.81 - 9.92], p = .0785), epilepsy (2.47 [0.98 - 6.59], p = .0536), ASD (1.32 [0.36 - 3.89], p = .7493), microcephaly (1.40 [0.47 - 3.72], p = .5882), and a developmental delay in the domains speech (1.89 [0.60 - 8.34], p = .4167) and motor skills (2.17 [0.69 - 9.55], p = .2223) (Figure 2A and B).

Discussion

In this study, we recruited a clinical cohort of 208 mothers and their children and analyzed the prevalence of maternal SYN1 autoantibodies and their association with developmental phenotypes. SYN1 IgG autoantibodies were detected through CBA in 9.6% of mothers with neurologically sick children. Most of the SYN1 CBA positive cases were negative on Western blots under denaturing conditions, suggesting a conformational dependency of their target binding, as similarly observed in other human anti-neuronal autoantibodies (18). In the study by Höltje et al. in a cohort of patients with various psychiatric and neurological disorders and SYN1 autoantibodies, binding was detected in immunoblots in about half of all patients (14). It is unclear whether in less denaturing conditions more SYN1 CBA positive cases would be positive. As in this study, we found IgG binding in immunoblots of 263
pregnant women screened for synapsin I autoantibodies in only 22.9% and found no correlation between ELISA and CBA antibody levels (16).

SYN1 is member of the family of synapsins, encoded by the three genes SYN1, SYN2, and SYN3 in humans. SYN1 regulates the trafficking of synaptic vessels between the readily releasable pool and reserve pool. Furthermore, Syn1 moderates neuronal development through neurite outgrowth and synaptogenesis (2). Syn1 mutant mice have severe epilepsy with generalized seizures (19).

We recently reported on a cohort of 263 pregnant women with seropositivity for SYN1 autoantibodies in 13.3%, matching the prevalence in this cohort (16). Seropositivity was associated with abnormalities of fetal development including intrauterine growth retardation. In this study of 208 children with various neurologic disorders, a positive maternal CBA showed a strong association with ID and behavioral problems, while there was a trend towards other abnormalities such as macrocephaly and epilepsy. This is intriguing given that patients with LoF variants in SYN1 display a similar phenotype with epilepsy, ID, ASD, macrocephaly, and behavioral problems (3-5). The lack of a clear association to these phenotypes can possibly be explained by the low statistical power of the study, requiring larger cohorts. In addition, due to the monocentric design and subsequent selection bias, multicenter studies need to be conducted to increase power.

When further analyzing the 20 CBA-positive patients seven had identified genetic variants/microdeletions of which one was considered pathogenic and three as likely pathogenic variants. This raises speculation as to whether genetic alterations in brain proteins may lead to neoantigen formation and increased autoimmunity. It is unclear whether maternal autoantibodies against SYN1 have a direct pathogenic effect on fetal development or rather represent a clinical biomarker of neuronal cell damage. It has been shown that SYN1 autoantibodies can reach the cytoplasmic site through
FcγII/III-mediated endocytosis and thereby replicating the molecular SYN1 LoF phenotype \textit{in vitro} (20). Other experimental studies have demonstrated the direct pathogenic effect of maternal antineuronal autoantibodies such as NMDAR, Caspr2, and aquaporin-4 antibodies (10-13). Further, Caspr2 autoantibodies present during pregnancy are associated with ID and developmental disorders (21). However, functional studies on the effects of SYN1 autoantibodies on neurodevelopment are lacking and should be performed at molecular resolution using patient-derived monoclonal antibodies (22).

Although this study has several limitations, due to the heterogeneity of the pediatric cohort, it indicates a potential influence of maternal SYN1 autoantibodies on neurodevelopment. Further prospective studies are needed in which pregnant women are tested for maternal autoantibodies and their child's development is closely monitored. Although these results do not currently trigger any direct therapeutic or diagnostic consequence, they could influence standard treatment of pregnant women in the long term and possibly lead to new therapeutic approaches.
