Abstract

Self-reported measures of height and weight are widely used in epidemiological studies. However, misreporting may bias estimates of associations between anthropometry and health outcomes. Further, few validation studies have compared self-reported and measured waist circumference (WC). This study aimed to quantify the agreement between self-reported and measured height, weight, body mass index (BMI), WC, and waist-to-height ratio (WHtR), and to investigate associations of these anthropometric measures with cardiometabolic biomarkers.

Self-reported and measured anthropometric variables, as well as cardiometabolic biomarkers, were obtained from participants aged above 18 years at recruitment into the Diet, Cancer, and Health-Next Generation Cohort in 2015-19 (N=39,514). Pearson correlations (r) and Lin’s concordance correlations were applied to evaluate misreporting. Misreporting by age, sex and smoking status was investigated in linear regression models. Multivariable regression models and Receiver Operating Characteristic analyses assessed associations of self-reported and measured anthropometry with cardiometabolic biomarkers. Self-reported height was overreported by 1.07 cm, and weight was underreported by 0.32 kg on average. Self-reported BMI and WC were 0.42 kg/m^2 and 0.2 cm lower than measured, respectively. Self-reported and measured height, weight, BMI, WC and WtHR were strongly correlated (r=0.98, 0.99, 0.98, 0.88, 0.86, respectively). Age, sex, smoking, and BMI contributed to misreporting of all anthropometric measures. Associations between self-reported or measured anthropometric measures and cardiometabolic biomarkers were similar in direction and strength. Concordance between self-reported and measured anthropometric measures, including WC, was very high. Self-reported anthropometric measures were reliable when estimating associations with cardiometabolic biomarkers.
Introduction

In epidemiological studies, anthropometric variables are usually self-reported, especially in large study populations, as it is cost-effective and less burdensome compared to clinical measurements. However, data may be subject to systematic errors because of observer bias or recall bias[1]. These reporting errors may be related to age, sex, race, education, and level of BMI[1, 2]. Several observational studies have assessed the concordance between self-reported and measured height and weight indices, and found a tendency towards overestimated height and underestimated weight, which led to an underestimate of BMI[3, 4]. The measurement error in self-reported BMI and other anthropometrics might bias estimates of associations with health outcomes, such as CVD, T2D, various types of cancer, and mortality[5-10]. However, only few cohorts have recorded both measured and self-reported anthropometrics at recruitment, and very little is known about how misreporting influences associations in different subgroups, for example whether there are discrepancies between younger and older participants. Furthermore, misreporting of central adiposity, as measured by waist circumference (WC) or waist-to-height ratio (WHtR), has generally not been investigated in validation studies, thus reliable comparison of self-reported and measured central adiposity-health outcome associations is lacking.

In this study, we examined the strength of association between measures and indices of general obesity, abdominal obesity, and metabolic profiles using data from the Danish Diet Cancer and Health-Next Generations (DCH-NG) cohort with adult participants. The objectives of this study were to investigate: (1) the extent of misreporting in self-reported height, weight, BMI, WC, and WHtR; (2) factors associated with misreporting; (3) comparisons of general obesity and abdominal obesity classification by self-reported and measured BMI and WC; (4) comparisons of associations of height, weight, BMI, WC, and
WHtR with cardiometabolic biomarkers for self-reported and measured anthropometric
measures.

Materials and methods

2.1 Study design and participants

The DCH-NG was established between August 2015 and April 2019 as an extension of the
Danish Diet, Cancer and Health (DCH) cohort. The DCH and DCH-NG study design and
methods have been described elsewhere[11, 12]. Briefly, the DCH cohort included 57,053
men and women who were born in Denmark, aged 50–64 years, had no cancer diagnosis
registered in the Danish Cancer Registry and lived in the area of Copenhagen or Aarhus at the
time of recruitment in 1993–1997[12]. In 2015-2019, children of DCH cohort members (G1),
their spouses (G1P) and grandchildren (G2) were invited to participate in the DCH-NG study,
which aimed to investigate associations between genes, diet, and lifestyle across generations.
The inclusion criteria included: individuals were listed in the Danish Civil Registration
System (registers all persons alive and having a valid address in Denmark)[13], alive at the
date of recruitment, and were above 18 years of age at the time of recruitment (born before
January 1st, 2000). If a woman was pregnant at the planned time of recruitment, she was
invited to participate after giving birth. Grandchildren (G2) were only invited if their parent
(G1) was alive and eligible for invitation. 255,608 descendants were identified and 197,639
fulfilled the inclusion criteria. 13,875 descendants were excluded due to their status in the
CPR (e.g. hidden address or inactive status in CPR). A total of 183,764 individuals were
invited by letter and 44,869 agreed to participate in the DCH-NG (Fig 1). The Diet, Cancer
and Health – Next Generations research project was approved by the Danish Data Protection
Agency ((journal number 2013–41–2043/2014–231-0094) and by the Committee on Health
Research Ethics for the Capital Region of Denmark (journal number H-15001257)[11].
Participants provided informed consent.
2.2 Anthropometric measurements and biomarkers

Measured body weight, height, and WC

Participants were invited to complete a physical examination in a study center in Copenhagen or Aarhus. Height, weight, and WC were measured by trained and certified health researchers. Anthropometric measurements were assessed with participants wearing underwear and being barefoot. Height was measured to the nearest 0.1 centimeter (cm) using a wireless stadiometer (Seca 264). Weight was measured to the nearest 0.01 kg using a body composition analyser (Seca 515/514). WC was measured midway at the midway between the lower rib and the iliac crest and recorded to the nearest 0.1 cm. WC was obtained in duplicate; a third measurement was taken if the first two measures exceeded pre-specified differences (1.0 cm). The mean of the two closest measures was used for analyses. BMI was calculated using the standard formula weight (kg) divided by height squared (m²), then classified into 4 categories: underweight (<18.5 kg/m²), normal weight (18.5–24.9 kg/m²), overweight (25–29.9 kg/m²), and obese (>=30 kg/m²) according to WHO recommendation[14]. WHtR was calculated by the formula WC in cm divided by standing height in cm. Abdominal obesity was defined by the National Institutes of Health cutoff points[15], as a WC of 102 cm or greater for men and 88 cm or greater for women. Discrepancies between self-reported and measured height of over 10 cm and between self-reported and measured weight of over 5 kg were checked for data-entry errors.

Blood pressure and metabolic biomarkers

Blood pressure was measured in a seated position after the participant had rested for at least 5 min. After measurement of the circumference of the mid-upper arm, a cuff of suitable size was applied to the participant’s upper arm, which was supported by the table at heart level.
Systolic blood pressure (SBP) and diastolic blood pressure (DBP) were taken three times using the Omron M-10 IT, and the set with the lowest values of SBP and DBP was used.

Participants were non-fasting, but were asked not to eat a fatty meal, consume alcohol, use chewing gum, brush teeth or similar within two hours before their visit to the study center. Whole blood and lithium-heparin blood samples were taken for upfront analyses performed after the visit in the study center. The following biomarkers were assessed: hemoglobin A1c (HbA1c, mmol/mol), total cholesterol (mmol/L), triglycerides (TG, mmol/L), HDL (mmol/L), low-density lipoprotein (LDL, mmol/L), C-reactive Protein (CRP, mg/L) and creatinine (μmol/L).

**Definition of hypertension, dyslipidemia, and pre-diabetes**

Hypertension was defined as having a blood pressure of >140/90 mmHg according to the WHO guidelines[16]. Dyslipidemia was defined as having TG >2.0 mmol/l or HDL < 1.0 mmol/l based upon the recommendations by the National Heart Foundation[17] and the Australian Diabetes Society[18]. Pre-diabetes and diabetes was defined as HbA1c of >42 mmol/mol (>6.0%)[19].

**Lifestyle questionnaire**

Self-reported anthropometric measures were obtained from a web-based lifestyle questionnaire (LSQ), which was provided to the participants shortly after recruitment. Respondents were asked: ‘How much do you weigh? Enter the nearest whole kg’; ‘How tall are you in cm’, and ‘What is your waist measurement in cm?’ Respondents were provided with guidance similar to that used in the study center on where to place a tape measure for WC measurement. Smoking status was categorized as current, former, and never smoker.
2.3 Statistical analysis

Continuous measures are presented as mean ± standard deviation (SD) if normally distributed and median/interquartile range (IQR) if no normal distribution could be assumed. Categorical variables are shown as percentages.

Misreporting of anthropometric measures was calculated by subtracting measured from self-reported values. Bland-Altman analysis was used to compare the degree of agreement between self-reported and measured measurements, which gave the mean and 95% prediction interval of the difference between objective measurements and self-reported values[20].

Pearson's correlation coefficients (r) between self-reported and measured anthropometrics were calculated. In addition, concordance was evaluated using Lin's concordance coefficient (p_c), which is a reliability measure indicating the agreement between two measures of the same variable. To assess the agreement between measured and self-reported prevalence of general obesity and abdominal obesity, Gwet’s agreement coefficient was applied. Coefficients greater than 0.81 were considered almost perfect[21]. Multiple regression analyses were used to evaluate which factors were associated with the misreporting between measured and self-reported anthropometrics (weight, height, BMI, WC, WHtR). The following variables were included in the regression models as independent variables: sex, age groups, measured BMI categories, and smoking status.

Correlation and multivariable regression analyses were conducted to examine the cross-sectional relationships of cardiometabolic biomarkers with self-reported and measured anthropometric indices (BMI, WC, WHtR). Outcome variables with skewed distributions (TG, HbA1c, CRP, and creatinine) were log-transformed for the analyses. Model 1 was unadjusted model and model 2 was adjusted for sex, age (continuous) and smoking status.
Analyses were repeated using standardized coefficients. We further stratified all the analyses by different age groups to explore potential effect modification. Receiver Operating Characteristic (ROC) analyses were conducted to assess the diagnostic accuracy of disease conditions (hypertension, dyslipidemia, and pre-diabetes) by different anthropometric measures or indices. An area under the curve (AUC) of 1 is considered to have perfect discriminatory power, and an AUC of 0.5 indicates the predictive performance is no better than chance. AUCs of 0.6–0.7 were considered poor and 0.7–0.8 fair. Optimal cut-offs on the ROC curves were chosen to maximize sensitivity and specificity of the variables with each above 50%. Sensitivity in this report was defined as the proportion of people which were categorized as positive with the disease condition, while specificity was the proportion of people which were categorized as negative without the disease condition.

Sensitivity analyses

In sensitivity analyses, we further assessed whether completing the LSQ before going to the study center or after made a difference to the results. The statistical software packages Stata/IC 16.0 (StataCorp)[22] and R (v4.0.2)[23] were used to conduct the analyses. All P-values were two-sided, and a P < 0.05 was considered statistically significant.

Results

Characteristics of the study subjects

39,514 participants were included in the analyses (Fig 1). Descriptive statistics for demographic characteristics are presented in S1 Table. The median age of the cohort population was 48 years (IQR: 32-54 years). 42% of the participants were men (n=16,560). More than half of the participants reported never smoking, 32.5% of the participants were classified as being overweight and 11.9% as obese based on BMI derived from measured
heights and weights. Compared with women, a larger proportion of men were overweight or obese (overweight: 42.1% male vs 25.5% female; obese: 12.7% male vs 11.3% female).

Fig 1. Flowchart illustrating the participant route into the study

*Status includes inactive and invalid vital status, hidden address and invalid address.

Factors associated with misreporting of anthropometrics
Table 1 presents the summary statistics for self-reported and measured anthropometrics. Self-reported height was 1.07 cm (SD=1.71 cm) higher than measured height, while weight was 0.32 kg (SD=2.15 kg) lower than measured. As a result, BMI calculated from self-reported values was 0.42 kg/m² (SD=0.89 kg/m²) lower than measured BMI. More than 77 percent of the deviations of self-reported BMI from measured BMI did not exceed values within 1 unit (data not shown). 33% of the participants did not report their WC, but answered ‘do not know’ or ‘do not have a tape measure’. Participants who were male, of younger age, higher BMI and currently smoking were more likely to be missing self-reported WC. For those with available data, self-reported WC was underestimated by 0.20 cm (SD=6.04 cm). The variances of WC were larger for both self-reported and measured values, compared with other anthropometric measures. Men tended to overreport height (1.21 cm for men and 0.97 cm for women), while women tended to underreport weight (0.11 kg for men and 0.47 kg for women). Compared to women, men had relatively lower misreporting of WC (0.12 cm for men and 0.25 cm for women). However, there was no strong evidence that WHtR was different when calculated using self-reported and measured data (Table 1). Over-reporting of height and under-reporting of weight were present across all age subgroups, but the extent of misreporting was greater among older participants, especially for those above 55 years. Participants who were overweight or obese were more likely to misreport height, weight, and WC compared to participants of measured normal BMI. Underreporting of weight and BMI were more evident in former smokers, while WC variance was larger in current smokers (S2 Table). Multiple linear regression analyses indicated that age, sex, smoking and overweight/obese status all contributed to misreporting of all anthropometric indices (S3 Table).

Reliability of self-reported anthropometric variables
Comparably high correlations were found among all self-reported and measured anthropometric variables. The correlation coefficients for height, weight, BMI, WC, and WHtR were 0.98, 0.99, 0.98, 0.88, 0.86, respectively. Similarly, Lin’s concordance correlations were 0.98, 0.99, 0.97, 0.88, 0.86. Bland-Altman analysis indicated no significant differences among self-reported and measured weight, height, BMI, and WC (Table 2).

BMI categories were calculated from both self-reported and measured values. The prevalence of overweight and obesity were 32.5% and 11.7% from measured BMI, but only 29.7% and 9.8% from self-reported BMI, indicating underestimation of self-reported BMI (S4 Table). Using self-reported data, 80.4% and 79.7% were correctly classified as overweight and obese (S5 Table). Agreement in classification by self-reported and measured BMI and WC, assessed by Gwet’s agreement coefficients, is shown in S6 Table. When BMI was categorized into 4 groups according to WHO’s criteria, Gwet's agreement coefficient between self-reported and measured BMI categories was 0.86 (95%CI: 0.86, 0.87); the agreement was 0.97 (95%CI: 0.96, 0.97) when BMI was categorized into 2 groups (normal vs overweight and obese). For WC, the agreement between self-reported and measured values was 0.84 (95%CI: 0.83, 0.85).

Associations between anthropometric measures and cardiometabolic biomarkers

The associations between anthropometric measures and metabolic biomarkers are presented as standardized (S7 Table) and unstandardized (S8 Table) linear coefficients. There were positive associations between the measures and TG, LDL, HbA1c, total cholesterol concentration, and blood pressure, respectively, and an inverse relationship with HDL concentration in both unadjusted and adjusted models. Using standardized coefficients, the associations with metabolic biomarkers did not vary substantially when comparing self-
reported and measured indices, although associations were stronger for measured WHtR and measured WC than for self-reported WHtR and WC (Fig 2). In stratified analyses, positive associations when examining central adiposity on total cholesterol, LDL, SBP and DBP were observed for early adulthood to middle-aged groups, whereas associations were weaker for participants above 55 years of age (S9 Table).

**Fig 2. Standardized coefficients of self-reported or measured anthropometrics and cardiometabolic biomarkers**

a) self-reported (orange color) or measured (blue color) BMI associated with cardiometabolic biomarkers

b) self-reported (orange color) or measured (blue color) WC associated with cardiometabolic biomarkers

c) self-reported (orange color) or measured (blue color) WHtR associated with cardiometabolic biomarkers

Models were adjusted for age, sex, and smoking.

TG triglycerides; HDL, high-density lipoprotein; LDL, low-density lipoprotein; HbA1c, hemoglobin A1c; CRP, C-reactive Protein; SBP, systolic blood pressure; DBP, diastolic blood pressure; BMI, body mass index; WC, waist circumference; WHtR, waist-to-height ratio; CVD, cardiovascular diseases

The prevalence of hypertension, dyslipidemia, and pre-diabetes were 23.2%, 5.5%, and 1.7%, respectively. The AUC for each anthropometric index with hypertension and dyslipidemia
indicated fair predictive performance, ranging between 0.7-0.8; prediction was excellent for pre-diabetes (above 0.8; Fig 3, S10 Table).

**Fig 3. ROC curves comparing measured and self-reported anthropometric indices with cardiometabolic biomarkers**

Green lines indicate measured anthropometrics, yellow lines indicate self-report anthropometrics, black lines indicate reference. Models were adjusted for age, sex, and smoking.

*ROC, Receiver Operating Characteristic*

In sensitivity analyses, the correlation between self-reported and measured height and weight was equal regardless of whether participants completed the LSQ before going to the study center or after, whereas the correlation between self-reported and measured WC was slightly higher among those completing the LSQ after going to the study center (0.93 vs 0.88) (S11 Table).
Discussion

In this large contemporary cohort, we found high agreement between self-reported and measured anthropometrics, albeit slightly lower for WC and WHtR than for other measures. Older age, male sex, weight status, and smoking contributed to misreporting. We compared the associations between self-reported or measured anthropometric variables and cardiometabolic biomarkers, and found similar directions and magnitudes across all age groups. Our results extend previous validation studies that only included certain specific age, ethnic, or BMI groups[24-31], which may limit generalizability to general population studies.

Our findings are in agreement with previous European validation studies[32-35]. Self-reported BMI may bias associations with health outcomes, despite high correlations between self-reported and measured values[5]. A US cohort study compared associations between self-reported and measured BMI and cardiometabolic biomarkers in young adults, and found similar strengths of association[4], as have studies in US adults[3, 6]. However, other studies have reported poor performance for self-reported anthropometric indices in predicting cardiometabolic related diseases[8, 36]. These differences may be explained by study design, different age groups, and approaches in adjusting for confounders. We found that the strength of associations with cardiometabolic biomarkers did not vary substantially for measured and self-reported indices. While associations were stronger for measured indices compared with self-reported, the bias was small.

We observed greater misreporting among older age groups, as well as differences in strengths of association between both measured and self-reported anthropometrics and cardiometabolic biomarkers across age groups. These results are, however, comparable to results from the
WHO MONICA Project, which found that the association between BMI and hypercholesterolaemia (cholesterol ≥ 6.5 mmol/l) was weaker in higher age groups[37]. Similar results were reported from a large scale Chinese study[38]. A possible explanation could be increasing fat mass and lower lean mass with increasing age[39].

Our study has several strengths. With self-reported and measured WC, we provide much needed assessment of central adiposity indices[40]. We included a wide age range, which allowed investigation of age on misreporting and associations. Finally, the DCH-NG cohort is a new cohort[11], and thus reflects contemporary trends in self-assessment of weight, height and WC.

The study also has limitations. Firstly, similar to the DCH cohort, participants in the DCH-NG cohort had a higher socioeconomic status relative to the nonparticipants[12]. Therefore, it is important to take into account the generalizability and representativeness of the current sample in regard to the general population when interpreting the results. Secondly, there was a higher proportion of missing data in self-reported WC than for other measures. Our sensitivity analyses suggested that younger people, those with greater BMI and who smoked tended not to report WC. However, the missingness was not related to measured WC values, and there was little missing data among those participants who completed the LSQ after having visited the study facility. It is likely that participants did not report WC values simply because they did not know their WC. Improving general knowledge about WC and related health outcomes may be useful from a public health perspective[41]. Lastly, some participants had a longer gap between filling in the questionnaires and the clinical appointments than others, which might influence the consistency of the measures. However,
the percentage of participants for whom this was the case was small and thus unlikely to bias the results.

Conclusion

This study found a high correlation between self-reported and measured anthropometric variables across a wide age range in the study population. The overall agreements with respect to the reporting of accurate values were reliable and acceptable. However, caution may need to be taken when generalizing the findings to other populations.
