Abstract

International air travel has been recognized as a crucial factor in the cross-regional transmission of monkeypox (now known as mpox) since this disease rapidly spread across the globe in May 2022. On September 6, 2022, Hong Kong SAR (HK) reported its first imported mpox case with travel history of the United States (US), Canada, and the Philippines. In this study, we estimated the importation risk to HK from 25 international departures from May 1 to September 6, 2022, based on the prevalence of pre-symptomatic mpox cases in the study regions, and time-varying flight mobility evaluated by aggregating multiple open-access air travel datasets (e.g., OpenSky, Aviation Edge). The result indicated that the US had the most significant importation risk of 0.63 (95% CI: 0.32, 0.95) during the study period, followed by the United Kingdom (UK) and Canada with a risk of 0.29 (95% CI: 0.10, 0.63) and 0.17 (95% CI: 0.08, 0.32), respectively. Our study demonstrated that the importation risk of mpox from the US and Canada was substantially higher than other regions, which was aligned with the travel history of the first reported case in HK. Our study provided a simplified computational method for estimating the importation risk of mpox virus based on air travel mobility and disease prevalence. Estimating the international importation risk of mpox is essential for appropriately designing and timely adjusting emergency public health strategies and inbound measures.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.
Keywords: mpox, monkeypox, importation risk, prevalence, international air travel, Hong Kong

Introduction

Mpox (monkeypox) is a zoonotic disease rarely transmitted outside Africa before 2022 (Nature 2022; S. Wang et al. 2022; Z. Du et al. 2022). On May 7, 2022, a confirmed case of mpox who traveled from Nigeria to the United Kingdom (UK) (“Monkeypox - United Kingdom of Great Britain and Northern Ireland” n.d.) was reported by the World Health Organization. After that, the rapid outbreak marked the first time that mpox spread widely in non-endemic countries, covering Europe, North America, and Oceania successively (“Multi-Country Monkeypox Outbreak in Non-Endemic Countries” n.d.). On July 23, 2022, World Health Organization declared the ongoing mpox outbreak as a Public Health Emergency of International Concern (PHEIC) (“WHO Director-General Declares the Ongoing Monkeypox Outbreak a Public Health Emergency of International Concern” n.d.). As of December 28, 2022, 83,751 cases had been reported in 110 countries or regions, with 9 countries reporting a high cumulative number of cases (≥3000), namely the US (n=29,554), Brazil (n=10,493), Spain (n=7,496), France (n=4,114), Colombia (n=4,021), UK (n=3,730), Germany (n=3,676), Peru (n=3,643), and Mexico (n=3,509) (Mathieu et al. 2022).

International air travel plays an essential role in the transmission of mpox (Talbot 2022). Most confirmed cases were with travel history from European and North American countries rather than West or Central Africa (“Monkeypox Outbreak” n.d.; Angelo et al. 2019). The first imported mpox case in Hong Kong SAR (HK), whose recent stops included the US, Canada, and the Philippines, was documented on September 6, 2022 (Reuters 2022a). The Government of Hong Kong has procured a third-generation vaccine, “JYNNEOS,” which has been licensed by the U.S. Food and Drug Administration (FDA) to protect against mpox (“Centre for Health Protection, Department of Health - Monkeypox” n.d.). Although rapid responses were quickly initiated in non-endemic areas, including vaccination and surveillance of human-to-human transmission, travelers from high-risk regions may still pose a potential importation risk to the destinations due to the long incubation period (Thornhill et al. 2022).

Various mathematical models and research methods have been developed to estimate the risk of cross-regional transmission. Previous research has provided vital insight into infectious disease transmission by combining travel data with local disease outbreak data (Shi et al. 2020; Kuo and Chiu 2021; Russell et al. 2021; Zhang et al. 2022). In the fight against COVID-19 outbreaks, the importation risk of COVID-19 (including the wildtype, 501Y, and Omicron sub-variants) is quantified based on the accessibility to the airline network and local disease situations to guide inbound control measures (Z. Du et al. 2021; Bai, Du, et al. 2022; Nakamura and Managi 2020; Z. Du et al. 2020; Bai, Xu, et al. 2022; Xu et al. 2022). The correlations between air travel and the international transmission of mpox have been clearly identified (Bhattacharya, Dhama, and Chakraborty 2022; M. Du et al. 2022; Kinoshita et al. 2022). These studies highlighted the importance of appropriately estimating the importation risk among air passengers to effectively mitigate the cross-regional transmission of infectious disease (Menkir et al. 2021; Lai et al. 2022; Han et al. 2021).

As a major international transportation hub and a special economic zone of China, HK has been affected by the global spread of infectious diseases over the past decades (Z. Du, Tian, and Jin 2022; Z. Du et al. 2023). HK experienced the SARS outbreak in 2003 (Pine and McHercher 2004) as well as the Influenza A (H1N1) pandemic in 2009 (Liao et al. 2010),
and further fueled and accelerated the global transmission of these diseases (National Immunization Advisory Committee (NIAC) Technical Working Group (TWG), Influenza Vaccination TWG 2021). The volume of air traffic from overseas to Hong Kong has been gradually increasing following the reopening of HK on August 12, 2022 (“Government Announces Lifting of Compulsory Quarantine Requirement on Arrival at Hong Kong” n.d.), understanding and nowcasting the international importation risk of the mpox virus is critical for designing appropriate emergency public health strategies and inbound measures to reduce transmission risk. Our study aims to quantify the importation risk of mpox by combining aviation transportation data and prevalence in origin regions estimated during the early stage of the emergency public health outbreak, using HK as a case study. We estimated the daily volumes of air travel passengers from international regions to HK via open-access aviation datasets (e.g., OpenSky (Meides n.d.), Aviation Edge (“Aviation API List” 2017)) and the prevalence of mpox by country from Our World in Data (Mathieu et al. 2022). We further estimated the probability of importing at least one mpox case between May 1 and September 6, 2022, before the date of the first mpox imported case. Our research included 25 regions covering four continents with the most reported cases and direct air connection to HK.

Materials and Methods

Data Source

To estimate the daily number of passengers traveling to HK, we aggregated the daily direct flights arriving (and landing) in HK by combining the results from the OpenSky (Meides n.d.) and Aviation Edge (“Aviation API List” 2017). The information for each airport and estimated passenger capacity per aircraft were obtained from OurAirports (“Open Data @ OurAirports” n.d.) and the Admtl (Aéroports de Montréal 2021), respectively.

We retrieved monthly data for about 696 thousand air-travel passengers arriving or transiting in HK during the study period \( T \) (from May 1 to September 6, 2022) (“Tourism Statistics” n.d.). In total, we extracted 20,181 direct and transit flights from 46 distinct regions, with 14,858 from OpenSky and 5,323 additional from Aviation Edge. Due to the lack of transit flight information, we assumed Hong Kong was the destination for every flight landing at Hong Kong International Airport. We obtained the 7-day smoothed daily reported cases of mpox of different countries and regions from Our World In Data (Mathieu et al. 2022) from May to September 2022.

Estimating daily air-travel passengers from international regions to HK

We first estimate the time-varying mobility via air travel following the methods used in ref. (Bai et al. 2022) and then calculate the prevalence of pre-symptomatic cases in a given area to estimate the likelihood of introductions. The notation and values of the parameters are provided in Table 1.

Given the lack of information regarding the actual composition of each flight, it was assumed that each flight was at full capacity. Used \( \Omega_o^a(t) \) is the daily volume of aircraft \( a \) from the international region \( o \) to HK and \( \delta_o \) is the maximum passenger capacity for aircraft \( a \) of all types of aircraft \( A \) (Aéroports de Montréal 2021). Thus, the approximated inbound passengers \( m_o^a(t) \) from \( o \) to HK on day \( t \) is given by: \( m_o^a(t) = \sum_{a \in A} \Omega_o^a(t) \times \delta_o \). Then, we validated the air traffic by defining the ascertainment rate of passenger volume \( Y_o^a(T) \) as the
ratio of actual and estimated passengers to adjust the probably overestimated air-travel passengers, given by:

\[ Y_o'(T) = \frac{\delta_o(T)}{\sum_{t,T} m_o'(t)} \]  

(1)

where \( \delta_o(T) \) stands for the actual passengers from the \( o \) during \( T \). For those regions without the monthly visitor statistics to HK (“Tourism Statistics” n.d.), we matched \( m_o'(t) \) and the ascertainment rate \( Y_o'(T) \) to estimate the daily inbound volume:

\[ M_o(T) = Y_o'(T) \times m_o'(t). \]

**Estimating pre-symptomatic prevalence of mpox**

We utilized 7-day smoothed mpox cases reported by region (Mathieu et al. 2022) to estimate the pre-symptomatic prevalence of mpox. Following the sub-exponential model (Chowell et al. 2016; Z. Du et al. 2022), we first estimated the confirmed case on day \( t \) during the early outbreak of epidemics by:

\[ I_o(t) = r[r(1-p)t + I_o(t_o)^{(1-p)}]^\left(1/(1-p)\right) \]  

(2)

where \( t_o \) indicates the date when the case was first detected in region \( o \) and \( I_o(t_o) \) the corresponding initial number, \( r \) and \( p \) are the growth rate and the deceleration of growth, respectively. We assume \( r \) and \( p \) follow the normal distributions and estimate their mean and standard variance based on the daily confirmed cases in the study region, using the Levenberg–Marquardt algorithm implemented in prior studies (Viboud, Simonsen, and Chowell 2016) to minimize the residual sum of squares (RSS) between the model output and the observed cases.

To calculate the total number of infected cases who had not yet developed symptoms \( \Phi_o(t) \), we back-shifted the time series of reported cases by incubation period \( D_i \):

\[ \Phi_o(t) = \sum_{i=-1}^{t-1} I_o(i) \]  

(3)

Then, we divided the total cases by the population size \( N_o \) of the origin \( o \) to calculate the prevalence of pre-symptomatic cases, which is given by \( P_o(t) = \Phi_o(t) / N_o \). For each simulation to yield the incidence in the region \( o \) during the study period, we independently simulate 1000 times to sample a pair of \( r \) and \( p \) from the normal distributions to introduce uncertainty.

**Estimating importation risk of mpox**

We assumed all the mpox cases (that had not developed symptoms among passengers who intended to travel to HK) would be able to board. To estimate the number of imported cases from each region, we combined air-passenger with the daily prevalence of mpox to yield the importation force of cases that have not developed symptoms. We assumed that the proportion of pre-symptomatic passengers departing from a region was the same as the overall prevalence of pre-symptomatic cases in that region. Thus, the imported cases from region \( o \) to HK on day \( t \), is given by:
Informed by the first case among inbound passengers reported in HK who might be infected in the US on September 6, 2022 (Reuters 2022a), we calibrated the cumulative number of imported cases from the US as 1 at the end of the study period. Based on the observed event by September 6, 2022, we normalized each origin region’s cumulative imported cases, by

\[ \hat{\Gamma}_o(t) = \Gamma_o(t) / \Gamma_{US}(t_o), \]

where \( \Gamma_{US}(t_o) = 1 \) denotes the observed imported cases from the US on \( t_o \) (September 6, 2022).

Assuming that the imported cases of mpox from the study region \( o \) to HK are essentially a non-homogeneous poisson process (Wang and Wu 2018; Silverstein et al. 2020), we estimated the cumulative probability of at least one infected case (Z. Du et al. 2021; Bai et al. 2022) being introduced from \( o \) to HK by \( t \) as:

\[ \Psi_o(t) = 1 - \exp \left[ - \int_{t_o}^t \hat{\Gamma}_o(i) \, di \right] \]  

### Results

We estimated the time-varying flight mobility from a given country to HK with multiple open-access air travel datasets and the prevalence of pre-symptomatic cases in each study region. We synthesized these results to calculate the likelihood of at least one imported case occurring before September 6, 2022. Two indicators for the international importation risk of mpox to HK, namely the cumulative volume of imported cases and the cumulative probability of importing at least one case, were estimated by combining the aviation transportation data and the prevalence in origin regions. The estimated importation risk for the 25 regions between May 1 and September 6, 2022 is shown in Table 2.

**Figure 1a** shows the estimated number of imported cases in HK by September 6, 2022. The x-axis designates the estimated cumulative imported cases. Among the 25 international regions included in this study, we estimated that the US imported the maximum cases at 1.0 (95% CI: 0.39, 2.89), followed by UK at 0.35 (95% CI: 0.10, 0.99), Canada at 0.19 (95% CI: 0.08, 0.38).

**Figure 1b** represents the curve of importation risk reflecting the cumulative probability of importing at least one mpox case among inbound travelers. Based on the observed sources of imported cases, only the US had a mean importation risk of 0.63 higher than 0.5 (95% CI: 0.32, 0.95) as of September 6, 2022. The UK and Canada are the following, with 0.29 (0.10, 0.63) and 0.17 (0.08, 0.32), respectively.

**Figure 2** displays the risk of importation of mpox for the study regions as of September 6, 2022, where the closer the color to red indicates a higher risk of importation in that region. Our study found that the risk from the US and Canada was relatively higher, which is aligned with the fact that the first reported case in Hong Kong had stayed in both countries before arriving and may have been infected there.

### Discussion

Human mobility patterns influence epidemiological risk (Gao and Liu 2013). The prevalence of a newly emerging infectious disease will most likely be determined by where it was first imported. In this study, we estimated the time-varying importation risk of mpox from 25 international regions to HK. Informed by the estimated arrival number of passengers and the
local prevalence of mpox in each international origin, we developed a statistical method to estimate the cumulative risk of importation of mpox by combining actual imported events in HK. Our results were aligned with reality, and the estimates of imported cases reflected the connectivity of air travel and the prevalence of mpox in the corresponding origin countries and regions.

Our findings emphasize the importance of enhancing surveillance against mpox among travelers in regions with a high importation risk of mpox. The cumulative risk of importation of a region is highly correlated with the aggregated air travel flow to HK and the prevalence of mpox in that region. The ranking of importation risk indicated that the US had the highest risk during the entire study period. The number of mpox cases in the US surged from July to August (CDC 2022b), and the number of travelers from the US continuously increased during this period as the gradual relaxation of Hong Kong’s bounder control (“Tourism Statistics” n.d.). Except for the US, where the imported cases have been observed, several non-endemic countries, including the UK, Canada, France, Germany, and the Netherlands, are also at relatively high risk of importation. A previous study based on the Risk Matrix Method (M. Du et al. 2022) drew a similar conclusion about the importation risk of mpox into China: The US had the highest importation risk of mpox and should be closely monitored. Globally, MSM (men who have sex with men) make up the majority of cases in the current outbreak (CDC 2022a). The mpox virus is typically transmitted by close, personal contact with groups who developed symptoms among healthcare workers, laboratory personnel, and people with “high-risk sexual practices” such as sex workers (Reuters 2022b).

Although the probability of importing a case of mpox via international aviation is extremely low at the end of August, implementing surveillance and contact tracing for passengers with high-risk activities from specific areas would effectively contain the cross-regional spread of mpox.

Several assumptions and limitations should be discussed in our estimations. First, due to no access to the complete commercial aviation dataset, we postulated that air travels between regions are all directed, while the indirect travels should also be included in the air traffic volumes. This may cause the incorrect estimation of the passenger volumes to HK. We expect that combining complete passenger data with flight transit information would improve the accuracy of estimates of potential importation risks from international departures, but would not substantially change the analysis results. Second, our method for estimating mpox prevalence relies on the number of reported cases in the early phase of an outbreak. Given the varieties in monkeypox surveillance capacity in different regions and the delay between infection and case reporting (“Monkeypox 2022 Global Epidemiology; Report 2022-09-23” n.d.), the resulting undetected cases may lead to underestimate local pre-symptomatic prevalence. Third, we assumed that only infected cases who had not developed symptoms could board following prior studies (Z. Du et al. 2021). While in reality, some individuals with asymptomatic or mild infection may also be able to go aboard (De Baetselier et al. 2022). Obtaining data on the proportion of mild and asymptomatic infection in the real world would improve our estimates of mpox importation risk among air travelers. Fourth, our study only examined the importation risks posed by air travelers, hence the results cannot be extrapolated to other transportation routines (Menkir et al. 2021; Gao et al. 2022).

Conclusions

To conclude, our study provided a simplified computational method for estimating the mpox virus importation risk based on air travel mobility and disease prevalence. The approach can be adjusted to incorporate prevalence estimates and flight data from any origin and
destination locations requiring minimum data. Our findings emphasize the necessity for a more comprehensive understanding of the probable sources of case importation for predictive simulation and risk perception. Reliable estimates of international importation risk from an endemic or non-endemic area will benefit in accurately evaluating the potential need to curtail the cross-regional transmission of the mpox virus as well as the implementation of disease monitoring and preparedness.
