Abstract

Background: Tumour-promoting inflammation is a “hallmark” of cancer and conventional epidemiological studies have reported links between various inflammatory markers and cancer risk. The causal nature of these relationships and, thus, the suitability of these markers as intervention targets for cancer prevention is unclear.

Methods: We meta-analysed 6 genome-wide association studies of circulating inflammatory markers comprising 59,969 participants of European ancestry. We then used combined cis-Mendelian randomization and colocalisation analysis to evaluate the causal role of 66 circulating inflammatory markers in risk of 30 adult cancers in 338,162 cancer cases and up to 824,556 controls. Genetic instruments for inflammatory markers were constructed using genome-wide significant \( (P < 5.0 \times 10^{-8}) \) cis-acting SNPs (i.e. in or \( \pm 250 \) kb from the gene encoding the relevant protein) in weak linkage disequilibrium \( (\text{LD}, r^2 < 0.10) \). Effect estimates were generated using inverse-variance weighted random-effects models and standard errors were inflated to account for weak LD between variants with reference to the 1000 Genomes Phase 3 CEU panel. A false discovery rate (FDR)-corrected \( P \)-value (“\( q \)-value”) < 0.05 was used as a threshold to define “strong evidence” to support associations and \( 0.05 \leq q \)-value < 0.20 to define “suggestive evidence”. A colocalisation posterior probability \( \text{PPH}_4 \) > 70% was employed to indicate support for shared causal variants across inflammatory markers and cancer outcomes.

Results: We found strong evidence to support an association of genetically-proxied circulating pro-adrenomedullin concentrations with increased breast cancer risk (OR 1.19, 95% CI 1.10-1.29, \( q \)-value=0.033, \( \text{PPH}_4 \)=84.3%) and suggestive evidence to support associations of interleukin-23 receptor concentrations with increased pancreatic cancer risk (OR 1.42, 95% CI 1.20-1.69, \( q \)-value=0.055, \( \text{PPH}_4 \)=73.9%), prothrombin concentrations with decreased basal cell carcinoma risk (OR 0.66, 95% CI 0.53-0.81, \( q \)-value=0.067, \( \text{PPH}_4 \)=81.8%), macrophage migration inhibitory factor concentrations with increased bladder cancer risk (OR 1.14, 95% CI 1.05-1.23, \( q \)-value=0.072, \( \text{PPH}_4 \)=76.1%), and interleukin-1 receptor-like 1 concentrations with decreased triple-negative breast cancer risk (OR 0.92, 95% CI 0.88-0.97, \( q \)-value=0.15), \( \text{PPH}_4 \)=85.6%). For 22 of 30 cancer outcomes examined, there was
little evidence ($q$-value $\geq 0.20$) that any of the 66 circulating inflammatory markers examined were associated with cancer risk.

**Conclusion:** Our comprehensive joint Mendelian randomization and colocalisation analysis of the role of circulating inflammatory markers in cancer risk identified potential roles for 5 circulating inflammatory markers in risk of 5 site-specific cancers. Contrary to reports from some prior conventional epidemiological studies, we found little evidence of association of circulating inflammatory markers with the majority of site-specific cancers evaluated.
**Background**

Emerging evidence implicates chronic inflammation in cancer development [1-3]. Preclinical studies have shown that pro-inflammatory cytokines (e.g. tumour necrosis factor-α, interleukin-1, interleukin-6) promote cancer cell proliferation, invasion, and metastasis, and transcription factors for these markers (e.g. NF-kB and STAT3) are up-regulated across most cancers [4-8]. Prospective observational studies have reported associations between circulating inflammatory markers and risk of cancer across various anatomical sites [9-23]. Further, pharmacological inhibition of key inflammatory mediators (e.g. COX enzymes, interleukin-1β) in clinical trials has led to reduced risk of site-specific cancers [24, 25]. These successful trial results suggest that pharmacological targeting of other inflammatory markers identified in the observational epidemiological literature could be an effective approach for cancer prevention [26].

However, there are important challenges that accompany the translation of findings from observational studies into effective cancer control strategies. This is because of the susceptibility of conventional observational designs to various biases such as residual confounding (e.g. due to unmeasured or imprecisely measured confounders) and reverse causation [27, 28]. These biases frequently persist despite statistical and methodological efforts to address them [29-31], making it difficult for observational studies to reliably conclude that a risk factor is causal, and thus a potentially effective intervention target [32].

Mendelian randomization (MR) uses germline genetic variants as instruments (“proxies”) for risk factors to generate estimates of the effects of these factors on disease outcomes in observational settings [32, 33]. Since germline genetic variants are quasi-randomly assorted at meiosis and are fixed at conception, MR analyses should be less susceptible to conventional issues of confounding and cannot be influenced by reverse causation bias. In addition, MR analysis considers the long-term effect of risk factors on health outcomes, which is relevant in the context of diseases like cancer where there may be long induction periods between exposure to a particular risk factor and disease initiation [34].
Previous MR analyses that have examined the association of circulating inflammatory markers with cancer risk have been restricted to examining single inflammatory markers [35-41], individual cancer sites [36, 37, 42, 43], or have evaluated the effects of specific classes of inflammatory markers (i.e. cytokines) [44-46]. To date, however, no studies have used a systematic approach to comprehensively evaluate different classes of circulating inflammatory markers across adult cancers.

We aimed to systematically evaluate the causal relationship of circulating inflammatory markers with risk of 30 adult cancers. First, we performed a meta-analysis of genome-wide association studies (GWAS) of circulating inflammatory markers to generate novel and stronger genetic instruments for these markers. Second, we used the Open Targets Platform to identify inflammatory markers with prior evidence from preclinical and/or epidemiological studies to support their aetiological role in site-specific cancers and tested relationships of these inflammatory marker-cancer pairs using combined Mendelian randomization and colocalisation analysis (“Validation analyses”). Third, for all remaining inflammatory-marker cancer pairs, we systematically tested their relationship using combined Mendelian randomization and colocalisation analysis to identify potential novel circulating inflammatory markers implicated in cancer risk (“Discovery analyses”).

**Methods**

**Identification of inflammatory markers**

We compiled a list of all inflammatory markers that corresponded to one or more of the following classes: acute phase proteins, chemokines, growth factors, interferons, interleukins, and tumour necrosis factors [47-53]. Inflammatory markers were then mapped to their UniProt ID, resulting in 218 unique markers [54].

**Identification of GWAS for inclusion in meta-analysis**
GWAS of circulating inflammatory markers were included in meta-analyses if they met the following criteria: i) the study was performed in individuals of European ancestry, ii) the study was adjusted for basic covariates only (e.g. age, sex, principal components of genetic ancestry) to avoid issues due to potential collider bias, iii) effect estimates were presented in standard deviation (SD) units or equivalent (e.g. protein concentrations were inverse-normal rank transformed), and iv) complete summary genetic association data were available for cis-acting SNPs (i.e. ±250 kb from the gene encoding each marker). Where two studies with > 50% sample overlap measured the same protein, we selected the larger study for inclusion into the meta-analysis. In total, 6 studies met all inclusion criteria and 8 were excluded [55-60]. A summary of each included study is presented in Table 1 and a list of excluded studies along with their justification for exclusion is presented in Supplementary Table 1.

Data pre-processing and quality control

For each inflammatory marker of interest, UniProt IDs were mapped to proteomic platform-specific IDs based on annotations provided by platform vendors and manual review [61]. In quality control, 14 markers with the following issues were flagged and removed from one or more studies: those with ambiguous or duplicate Uniprot IDs, unique Uniprot IDs with duplicate probes, genes located on chromosome X, or proteins where summary genetic association data could not be accessed from the relevant data repository (Supplementary Table 2). After removal of problematic inflammatory markers, genetic association data for 204 of 218 markers of interest were available in at least one study. For each of these markers, the relevant protein-coding gene for the marker was identified using the UniProt ID mapping function and genomic coordinates for the gene (build GRCh37) were extracted using BioMart [62]. Of the 204 inflammatory markers, 116 markers were only measured in one study with the remaining 88 markers taken forward to meta-analysis.

GWAS meta-analysis to develop genetic instruments for inflammatory markers
Across all studies, summary genetic association data for each marker were extracted for cis-acting variants (i.e. ±250 kb from the gene encoding the protein). Genomic coordinates in Gilly et al. were converted from build GRCh38 to GRCh37 prior to data extraction using LiftOver [63]. All SNPs with a minor allele frequency (MAF) < 0.01 and all palindromic SNPs with a MAF > 0.40 were removed. For inflammatory markers measured in both Sun et al. and Folkersen et al., summary genetic association data from Sun et al. were not included in meta-analyses due to participant overlap across studies [55, 60]. Meta-analyses across inflammatory markers were performed using inverse variance-weighted fixed-effects models in METAL [64]. Of the 88 inflammatory markers included in the meta-analysis, 45 had 1 or more genome-wide significant \((P < 5.0 \times 10^{-8})\) variants associated with that marker and, therefore, were included in subsequent MR analyses.

**Pair-wise comparison of SNP effects across studies**

To compare agreement of SNP effects across studies included in meta-analyses, standardised effect estimates for inflammatory markers were systematically compared across studies using Pearson correlation coefficients. These analyses were performed by extracting independent cis-acting SNPs \((r^2<0.01, \text{with reference to the 1000 Genomes Phase 3 CEU Panel})\) across two \(P\)-value thresholds \((P < 5.0 \times 10^{-8}, P < 5.0 \times 10^{-4})\) in PLINK. Pair-wise comparisons were not performed for Folkersen et al. and Sun et al. due to participant overlap across studies. Comparisons were performed by aligning effect directions of SNPs to the protein-increasing allele to prevent inflated Pearson correlation coefficients [65]. The median (interquartile range, IQR) agreement in study-level comparison was \(r=0.66 (0.24-0.84)\) when using a \(P < 5.0 \times 10^{-8}\) threshold and \(r=0.65 (0.45-0.85)\) when using a \(P < 5.0 \times 10^{-4}\) threshold.

**Genetic instrument construction**

Following meta-analysis, genome-wide significant \((P < 5.0 \times 10^{-8})\) SNPs for each inflammatory marker of interest were extracted and SNPs with evidence of heterogeneity of effect
across studies ($P_{het} < 0.001$) were removed. In total, 45 inflammatory markers included in meta-
analyses were retained and combined with 21 markers measured in a single study (i.e. not included in
the meta-analysis) that had 1 or more cis-acting genome-wide significant ($P < 5.0 \times 10^{-8}$) variant
associated with the marker [66]. Genetic instruments to proxy 66 circulating inflammatory markers
were constructed from SNPs that were permitted to be in weak linkage disequilibrium (LD, $r^2 < 0.10$),
increasing the proportion of variance in each marker explained by the instrument and, thus,
maximising instrument strength [67].

Cancer GWAS study populations

We obtained summary genetic association data from GWAS of 30 cancer outcomes
representing 12 anatomical sites and 18 cancer subtypes within these sites [68-78]. The median (IQR)
number of cases across GWAS of unique anatomical sites was 15,161 (8,288-33,604). Analyses in
each study were restricted to individuals of European ancestry. Further information on statistical
analysis, imputation, and quality control measures for these studies is available in the original
publications. A summary of the numbers of cases and controls across each cancer outcome is
presented in Supplementary Table 3.

Analytical approach

We employed a two-stage approach to evaluate the effect of circulating inflammatory markers
on cancer risk. We first attempted to validate previously reported inflammatory marker-cancer
associations from the preclinical and/or epidemiological literature using the Open Targets platform
(“Validation analyses”)[79]. The Open Targets platform integrates data (e.g. gene expression, animal
models, text mining, pathways and systems biology) from > 20 public sources and uses this data to
systematically build an “Overall association score” between drug targets and disease outcomes (i.e. a
summary of the overall evidence implicating a protein-coding gene in a disease outcome). All
inflammatory marker-cancer pairs with an “Overall association score” $\geq 0.05$ were included in
validation analyses (scores range from 0-1, where 1 represents strong evidence that a protein is implicated in a disease outcome). Of all remaining inflammatory marker-cancer pairs not included in “Validation analyses”, we then performed a “hypothesis-free” pan-cancer assessment to identify potential novel inflammatory marker-cancer associations (termed “Discovery analyses”).

Mendelian randomization can generate unbiased estimates of causal effects of exposures on disease outcomes if the following assumptions are met: i) the instrument is strongly associated with the exposure (“relevance”), ii) there are no common causes of the instrument and outcome (“exchangeability”), and iii) there is no direct effect of the instrument on the outcome (“exclusion restriction”). Under the assumption of monotonicity (i.e. the direction of the effect of the instrument on the exposure is consistent across all individuals), MR can provide valid point estimates for those participants whose exposure is influenced by the instrument (i.e. complier average causal effect)[80].

For inflammatory markers instrumented by a single SNP, the Wald ratio was used to generate effect estimates and the delta method was used to approximate standard errors. For markers instrumented by two or more SNPs, inverse-variance weighted (IVW) random-effects models were used to estimate causal effects [81]. Standard errors from IVW models were inflated to account for weak linkage disequilibrium between SNPs by incorporating a correlation matrix using the 1000 Genomes Phase 3 CEU reference panel [82, 83].

We evaluated the “relevance” assumption by generating estimates of the proportion of variance in each inflammatory marker explained by the instrument ($r^2$) and F-statistics. An F-statistic > 10 is conventionally used to indicate that instruments are unlikely to suffer from weak instrument bias [84]. Colocalisation analysis was performed to evaluate whether circulating inflammatory markers and cancer outcomes shared the same causal variant within a locus, necessary but not sufficient to infer causality between these traits. Such an analysis can also permit evaluation of whether circulating inflammatory markers and cancer endpoints are influenced by distinct causal variants that are in linkage disequilibrium with each other, indicative of horizontal pleiotropy (an instrument influencing an outcome through pathways independent to that of the exposure), a violation of the exclusion restriction assumption. Colocalisation analysis was performed by generating ± 250 kb windows from
the sentinel SNP used to proxy each inflammatory marker. We employed a colocalisation posterior probability (PPH₄) of > 0.70 to indicate support for shared causal variants across circulating inflammatory markers and cancer outcomes. All colocalisation analyses were performed using GCTA-COJO and the coloc package as implemented in Pair-Wise Conditional analysis and Colocalisation analysis (PWCoCo)[85-87]. We used default prior probabilities that any SNP within the colocalisation window was associated exclusively with inflammatory marker concentrations (p₁ = 1 x 10⁻⁴), exclusively with cancer risk (p₂ = 1 x 10⁻⁴), or both traits (p₁₂ = 1 x 10⁻⁵). Finally, iterative leave-one-out analysis was performed iteratively removing one SNP at a time from multi-SNP instruments to examine whether findings were driven by a single influential SNP.

To account for multiple testing, a Benjamini-Hochberg false discovery rate (FDR) correction was applied across “Validation” and “Discovery” analyses separately [88]. We used an FDR-corrected P-value (termed “q-value”) threshold of < 0.05 to define “strong evidence” to support analyses, with findings between q-value ≥ 0.05 and q-value < 0.20 defined as “suggestive evidence”.

Sensitivity analyses to explore potential aptamer or epitope binding effects

Genetic instruments may be associated with circulating protein concentrations due to aptamer or epitope binding artefacts when using protein assays that rely on binding (e.g. SomaScan)[89]. SNP associations in GWAS that employ aptamer-based protein platforms may therefore represent associations with protein measures due to differential binding rather than differences in protein abundance. As variants sensitive to aptamer or epitope binding effects tend to be missense variants, for two studies that used the aptamer-based SomaScan assay (i.e. Sun et al., Pietzner et al.), we flagged all instruments that were missense variants or variants that were in high LD (r² > 0.80) with a missense variant using functional consequence data from the Open Targets platform and the LDlinkR package [59, 60, 79, 90]. For top findings from “Validation” and “Discovery” analyses generated using multi-SNP instruments, as sensitivity analyses we then re-calculated MR estimates dropping missense variants or variants in high LD with missense variants from instruments. For top findings
consisting of single-SNP instruments that were missense variants or in high LD with a missense variant, we explored whether these instruments were also expression quantitative trait loci (eQTL) or splicing quantitative trait loci (sQTL) for the gene encoding the relevant inflammatory marker in the Genotype-Tissue Expression (GTEX) project V8. If missense variants (or variants in high LD with missense variants) also influence expression or alternative splicing of pre-mRNA of the gene encoding the relevant inflammatory marker, causal inference using these variants as instruments is unlikely to be biased even if effect estimates are invalid [91].

Expression quantitative trait loci enrichment to examine tissue-specific regulatory mechanisms of effects

For all top findings from “Discovery” and “Validation” analyses we examined whether instruments overlapped with eQTL \((P < 5.0 \times 10^{-8})\) to identify potential tissue-specific regulatory effects of instruments using data on 15,201 RNA-sequencing samples from 49 tissues of 838 post-mortem donors in the GTEX project V8 and 1,544 RNA-sequencing samples from 13 immune cells of 91 healthy subjects in the Database for Immune Cell Expression (DICE) [92, 93]. Where there was eQTL overlap, we then used multiple trait colocalisation (“moloc”) to evaluate colocalisation across circulating inflammatory marker concentrations, tissue-specific or immune cell-specific gene expression, and cancer risk [94]. We employed a colocalisation posterior probability > 0.70 to indicate support for shared causal variants across all three traits. We used default prior probabilities that any SNP within the colocalisation window was associated exclusively with inflammatory marker concentrations, tissue-specific or immune cell-specific gene expression, or cancer risk \((p_1 = 1 \times 10^{-4})\); associated with two of these traits \((p_2 = 1 \times 10^{-6})\); or associated with all three traits \((p_3 = 1 \times 10^{-7})\).

Evaluation of drug repurposing opportunities using DrugBank

For all findings showing “strong” or “suggestive evidence” in MR analysis and evidence of colocalisation, we used DrugBank to identify investigational and/or approved drugs targeting these
inflammatory markers [95]. The availability of drugs targeting these markers could suggest potential for their repurposing as pharmacological agents for cancer prevention.

A step-by-step overview of GWAS selection, instrument construction, and statistical analysis stages is presented in Figure 1.

Results

Across 66 circulating inflammatory markers, F-statistics for their instruments ranged from 30.0-7,608.0, suggesting that instruments were unlikely to suffer from weak instrument bias. Characteristics of genetic variants used to proxy circulating inflammatory markers are presented in Supplementary Table 4. Estimates of $r^2$ and F-statistics for each marker are presented in Supplementary Table 5.

Validation Mendelian randomization analyses

56 of the 66 inflammatory markers were included in validation analyses (i.e. markers with at least one cancer outcome with an overall association score $\geq 0.05$ in Open Targets). In total, 260 target-cancer associations were tested. In Mendelian randomization analysis, there was suggestive evidence to support 6 inflammatory marker-cancer associations. The strongest associations were for tumour necrosis factor ligand superfamily member 10 (TRAIL) concentrations and breast cancer risk (OR 0.90 per SD increase, 95% CI 0.85-0.95, q-value=0.072), circulating macrophage migration inhibitory factor (MIF) concentrations and bladder cancer risk (OR 2.46, 95% CI 1.48-4.10, q-value=0.072), and interleukin-7 receptor subunit alpha concentrations and colon cancer risk (OR 0.83, 95% CI 0.74-0.93, q-value=0.093)(Figure 2). Findings for all inflammatory marker-cancer associations that employed IVW models were robust to iterative leave-one-out analysis. In colocalisation analysis, there was evidence to support shared causal variants across circulating MIF concentrations and bladder cancer risk in the MIF locus (PPH4=76.1%), but little evidence to suggest
shared causal variants across 5 other inflammatory marker-cancer associations. Complete results from primary Mendelian randomization, iterative leave-one-out, and colocalisation analyses are presented in Supplementary Tables 6-8.

**Discovery Mendelian randomization analyses**

Among the 66 circulating inflammatory markers included in Discovery analyses, there was strong or suggestive evidence for 6 inflammatory marker-cancer associations. The strongest associations were for circulating pro-adrenomedullin concentrations and breast cancer risk (OR 1.19, 95% CI 1.10-1.29; \(q\)-value=0.033), interleukin-23 receptor concentrations and pancreatic cancer risk (OR 1.42, 95% CI 1.20-1.69; \(q\)-value=0.055), prothrombin concentrations and basal cell carcinoma risk (OR 0.66, 95% CI 0.53-0.81; \(q\)-value=0.067), serum amyloid P component concentrations and low grade serous ovarian cancer risk (OR 2.00, 95% CI 1.41-2.83; \(q\)-value=0.084), and interleukin-1 receptor-like 1 concentrations and triple-negative breast cancer risk (OR 0.92, 95% CI 0.88-0.97, \(q\)-value =0.15)(Figure 3). Findings for all inflammatory marker-cancer associations that employed IVW models were robust to iterative leave-one-out analysis. In colocalisation analysis, pro-adrenomedullin and breast cancer risk (PPH4=94.4%), interleukin-23 receptor and pancreatic cancer risk (PPH4=73.9%), prothrombin and basal cell carcinoma risk (PPH4=81.8%), and interleukin-1 receptor-like 1 and triple-negative breast cancer risk (PPH4=85.6%) showed evidence of shared causal variants across traits. Complete findings from primary Mendelian randomization, iterative leave-one-out, and colocalisation analyses are presented in Supplementary Tables 7-9.

**Evaluation of aptamer or epitope binding effects of instruments**

In sensitivity analyses exploring potential aptamer or epitope binding effects of instruments for Mendelian randomization findings showing evidence of colocalisation, one of two SNPs used to instrument interleukin-23 receptor concentrations (rs11581607) was in perfect LD \(\left(r^2=1.0\right)\) with a missense variant (rs11209026). Mendelian randomization findings were consistent when dropping this
SNP from the instrument and calculating a revised causal estimate (OR 1.40, 95% CI 1.10-1.78). In colocalisation analysis employing conditional analysis adjusting for rs11581607, evidence of shared causal variants across interleukin-23 receptor and pancreatic cancer risk associations persisted (PPH₄=69.8%). The SNP used to instrument prothrombin (rs3136516) was in high LD (r²=0.83) with a missense variant (rs2306029). There was evidence that rs3136516 is a sQTL for F2 (gene encoding prothrombin) in liver tissue (normalised effect size per copy of circulating prothrombin-increasing allele: 0.63, P=3.1 x 10⁻¹²). Functional annotation of SNPs used to instrument inflammatory markers along with SNPs in high LD with these variants is presented in Supplementary Table 10.

Expression quantitative trait loci overlap and multi-trait colocalisation analysis

Across 5 inflammatory markers with strong or suggestive evidence of association with cancer outcomes, there was evidence that the SNP used to instrument macrophage migration inhibitory factor concentrations (rs2330634) was an eQTL for MIF in 35 tissue types. There was little evidence of eQTL overlap for SNPs used to instrument the 4 other inflammatory markers. In multiple trait colocalisation analysis, there were low posterior probabilities of shared causal variants across circulating macrophage migration inhibitory factor, tissue-level MIF expression, and bladder cancer risk (a summary of eQTL overlap and findings from multiple trait colocalisation analysis is presented in Supplementary Table 11).

Genetic findings support drug repurposing opportunities in DrugBank

In DrugBank, of the 5 inflammatory markers showing evidence of a causal relationship with site-specific cancer, 3 of these markers (or related markers) are targets of approved or investigational medications. Though there are no approved medications that target the interleukin-23 receptor, three interleukin-23 inhibitors or antagonists (i.e. ustekinumab, tildrakizumab, risankizumab) have been approved to treat autoimmune conditions including moderate-to-severe plaque psoriasis [96, 97]. Several prothrombin activators or agonists have been approved for the treatment and prevention of
bleeding in individuals with haemophilia A (e.g. Moroctocog alfa, Lonoctocog alfa)[98, 99]. There are several investigational and experimental medications targeting macrophage migration inhibitory factor, but no approved drugs for this target to date. There were no investigational or approved inhibitors of pro-adrenomedullin or adrenomedullin or antagonists of adrenomedullin receptor subunits (calcitonin-receptor-like receptor, receptor activity-modifying protein 2, receptor activity-modifying protein 3) and no investigational or approved medications targeting interleukin-1 receptor like-1 or the interleukin-1 receptor like-1 ligand interleukin-33 in DrugBank. A summary of investigational and approved medications targeting the 5 inflammatory markers is presented in Supplementary Table 12.

Discussion

Our systematic Mendelian randomization and colocalisation analysis of 66 circulating inflammatory markers in risk of 30 cancers identified potential roles for 5 markers in risk of 5 site-specific cancers. We found suggestive evidence to implicate macrophage migration inhibitory factor concentrations in bladder cancer risk, consistent with prior reports, and identified potential novel associations between four other inflammatory markers (pro-adrenomedullin, interleukin-23 receptor, prothrombin, and interleukin-1 receptor-like 1) and risk of site-specific cancers. For 22 of 30 cancer outcomes examined (e.g. overall and subtype-specific lung, ovarian, and endometrial cancer), we found little evidence for association of circulating inflammatory markers with cancer risk despite evidence from conventional epidemiological studies suggesting roles of various markers evaluated in their aetiology [14, 18, 21, 22, 100, 101]. We also found little evidence that several putative key inflammatory mediators in cancer development (e.g. epidermal growth factor, interleukin-6 receptor, interleukin-8) were associated with cancer risk [102-104].

Some of the disagreement between our findings and those reported in the epidemiological literature could reflect the relatively limited sample size of some cancer outcomes included in our analyses (i.e. 13 of 30 outcomes were restricted to <10,000 cases). Alternatively, conflicting findings
could reflect the susceptibility of conventional epidemiological studies to unmeasured or residual confounding (e.g. due to imprecisely measured confounders) and reverse causation (e.g. latent, undiagnosed cancer influencing circulating inflammatory marker concentrations). Our findings therefore do not support widespread effects of those circulating inflammatory markers evaluated on cancer risk across several anatomical sites, though we cannot rule out small to modest or potential time-varying effects of these markers or potential heterogeneity of effects across participant subgroups (e.g. long-term smokers, individuals with autoimmune conditions).

In “Validation analyses” appraising previously reported inflammatory marker-cancer risk relationships, we found suggestive evidence for an association of genetically-proxied macrophage migration inhibitory factor concentrations with bladder cancer risk. MIF is a pleiotropic inflammatory cytokine and critical upstream mediator of innate immunity [105, 106]. *In vitro* studies of human bladder tissue have supported a role of MIF in tumour cell proliferation [107]. Further, in animal models of bladder cancer, *MIF* knockout mice displayed decreased angiogenesis and invasion as compared with wild-type mice and those administered oral MIF inhibitors had decreased growth and progression of tumours as compared to controls [108, 109]. Our findings, consistent with the preclinical literature, therefore suggest a potential role of MIF as a mediator of inflammation-driven bladder cancer and support the possible utility of pharmacological MIF inhibition as preventive therapy for this cancer.

In “Discovery analyses” examining potential novel inflammatory marker-cancer pairs, we found strong evidence for an association of genetically-proxied pro-adrenomedullin concentrations with breast cancer risk. Pro-adrenomedullin undergoes proteolysis and amidation to yield adrenomedullin and proadrenomedullin N-20 terminal peptide [110]. Adrenomedullin is a potent vasodilator that is expressed in breast cancer cells, upregulated by hypoxia in these cells, and has been shown to stimulate angiogenesis and tumour proliferation [111-113]. In addition, breast cancer cells overexpressing adrenomedullin show lower levels of various apoptotic factors (e.g. Bax, Bid, caspase 8) and murine models of breast cancer with adrenomedullin overexpression have accelerated bone metastasis and lower rates of survival [113, 114].
We also found suggestive evidence for an association of genetically-proxied interleukin-23 receptor concentrations with pancreatic cancer risk. The interleukin-23 receptor pairs with the interleukin-12 receptor β-1 subunit to mediate signalling of interleukin-23, a “master regulator” of innate and adaptive immunity and promoter of inflammatory mediators in the tumour microenvironment [115, 116]. Preclinical studies have reported that interleukin-23 can promote tumour metastasis through up-regulation of angiogenic factors and that interleukin-23 receptor blockade may confer protection against tumour growth [117, 118]. In addition, serum interleukin-23 concentrations are elevated in pancreatic cancer patients as compared to controls and higher expression of interleukin-23 in tumour tissues of patients is associated with advanced clinical stage [119, 120]. Four interleukin-23 inhibitors (i.e. ustekinumab, risankizumab, guselkumab, tildrakizumab) are currently approved for the treatment of immune-mediated inflammatory diseases such as plaque psoriasis [96, 97]. To date, clinical trials of these medications have not reported links with pancreatic cancer, though sample size (≤ 1,306 participants included in trials) and duration of follow-up of studies (i.e. median 24 weeks to 2.9 years follow-up across studies) have been limited [121-125]. Though further preclinical and epidemiological work is required to validate and clarify potential mechanisms governing this effect, our findings suggesting an adverse association of genetically-proxied interleukin-23 receptor concentrations with pancreatic cancer risk provide tentative support for a potential role for interleukin-23 inhibition or antagonism as a pharmacological approach for pancreatic cancer prevention.

Finally, there was suggestive evidence to support protective associations of genetically-proxied prothrombin concentrations with basal cell carcinoma and interleukin-1 receptor-like 1 concentrations with triple-negative breast cancer risk. Prothrombin is proteolytically cleaved to form thrombin, the end-product of the coagulation cascade that converts soluble fibrinogen to a fibrin clot. Preclinical studies have reported that thrombin can induce tumour growth, metastasis, and angiogenesis and that thrombin inhibitors suppress tumour growth and metastasis in some cancer cell lines [126-128]. In our analyses, the SNP used to instrument prothrombin was in high LD with a missense variant which could influence aptamer binding and produce biased effect estimates. Though
the SNP used to instrument prothrombin was also a sQTL for F2 (gene encoding prothrombin) in liver tissue, confident causal conclusions about the direction and magnitude of an effect of genetically-proxied prothrombin concentrations on cancer risk mediated via this variant cannot be made.

Interleukin-1 receptor-like 1 is the cognate receptor for interleukin-33, an epithelial-derived cytokine which has been reported to confer both pro- and anti-tumorigenic effects, depending on the tumour and cellular context, expression levels, and the nature of the inflammatory environment [129, 130]. Few studies have examined a potential role of interleukin-33 in triple-negative breast cancer risk though increased expression of this marker is associated with improved survival in triple-negative breast cancer risk [131]. The potential protective role of circulating interleukin-33 concentrations in triple-negative breast cancer risk requires further examination in future studies.

Strengths of this analysis include the comprehensive and systematic evaluation of a large number of circulating inflammatory markers, representative of different classes of inflammatory markers, in risk of 30 adult cancers. We used a dual “hypothesis-validating” and “hypothesis-generating” approach to attempt to validate previously reported inflammatory marker-cancer pairs and to identify potential novel inflammatory marker-cancer pairs. By performing a meta-analysis of 6 prior GWAS of circulating inflammatory marker concentrations we were able to generate stronger cis-acting instruments for inflammatory markers examined and to develop novel instruments for some markers, increasing statistical power and the breadth of analyses performed. The use of colocalisation as a sensitivity analysis permitted us to test the robustness of Mendelian randomization findings to confounding through linkage disequilibrium. Only 5 of 12 Mendelian randomization findings with “strong” or “suggestive” evidence of association were consistent in colocalisation analyses, highlighting the importance of evaluation of shared causal variants as further support for causality of traits examined, though we cannot rule out low power influencing findings from some of these analyses.

There are several limitations to these analyses. First, the presence or absence of associations of circulating inflammatory markers may not reflect potential tissue-specific effects of these markers in cancer development. While we examined tissue-specific regulatory mechanisms underpinning
effects of inflammatory markers showing strong or suggestive evidence of association with cancer risk, we did not systematically evaluate potential tissue-specific effects of genes encoding inflammatory markers across all cancer endpoints. Second, Mendelian randomization estimates represent the effect of long-term genetically-proxied inflammatory marker concentrations on cancer risk which may not correspond to the effect of pharmacological inhibition of these markers over relatively limited periods of time in clinical trials. Third, effect estimates presented assume no gene-environment or gene-gene interactions and linear and time-fixed effects of markers on cancer risk. Fourth, our analyses were restricted to cancer risk and not progression and therefore may not be informative of the utility of targeting inflammatory markers examined in the context of cancer treatment. Fifth, our analyses were performed in individuals of European ancestry and therefore the generalisability of these findings to non-European populations is unclear. Sixth, statistical power was likely limited for some rarer cancers and select cancer subtypes. Seventh, though various sensitivity analyses were employed to test robustness of our findings to potential violations of exchangeability and exclusion restriction assumptions, these assumptions are unverifiable. Eighth, we cannot rule out the possibility that the association of genetically-proxied prothrombin concentrations with basal cell carcinoma risk is driven through aptamer-binding effects given that the variant used to instrument this marker is in high LD with a missense variant. Finally, the inflammatory markers included in this analysis constitute a non-exhaustive list of inflammation-related markers which may influence cancer risk.

We found limited overlap of instruments for circulating inflammatory markers with tissue-specific or immune cell-specific eQTLs for the genes encoding these proteins which could plausibly reflect genetic effects on processes other than transcription, including protein degradation, binding, secretion, or clearance from circulation [60]. Systematic evaluation of the role of tissue-specific eQTLs for inflammation-related genes in cancer risk could provide further insight into tissue-level regulatory mechanisms influencing cancer development. There is a need to further replicate and validate findings, particularly for novel associations linking inflammatory markers to cancer risk identified in “Discovery” analyses. Future studies restricted to participant sub-groups with elevated
risk of cancer (e.g. life-long smokers, individuals with chronic inflammatory conditions) could aid in identification of inflammatory markers mediating cancer risk in these groups. Finally, evaluation of the potential role of circulating inflammatory markers in cancer prognosis could inform on the possible utility of the pharmacological targeting of these markers as cancer treatment.

Conclusion

Our systematic joint Mendelian randomization and colocalisation analysis of the effect of 66 circulating inflammatory markers in risk of 30 cancers suggests potential roles for 5 circulating inflammatory markers in risk of 5 site-specific cancers. Consistent with prior reports, we found suggestive evidence for a role of macrophage migration inhibitory factor in bladder cancer risk and strong or suggestive evidence for roles of 4 other potential novel inflammatory markers in site-specific cancer risk. Contrary to some previous conventional epidemiological studies, we found little evidence for association of circulating inflammatory markers with risk of the majority of cancer outcomes evaluated.

GECCO acknowledgments:

ASTERISK: We are very grateful to Dr. Bruno Buecher without whom this project would not have existed. We also thank all those who agreed to participate in this study, including the patients and the healthy control persons, as well as all the physicians, technicians and students.

CCFR: The Colon CFR graciously thanks the generous contributions of their study participants, dedication of study staff, and the financial support from the U.S. National Cancer Institute, without which this important registry would not exist. The authors would like to thank the study participants and staff of the Seattle Colon Cancer Family Registry and the Hormones and Colon Cancer study (CORE Studies).
CLUE II: We thank the participants of Clue II and appreciate the continued efforts of the staff at the Johns Hopkins George W. Comstock Center for Public Health Research and Prevention in the conduct of the Clue II Cohort Study. Cancer data was provided by the Maryland Cancer Registry, Center for Cancer Prevention and Control, Maryland Department of Health, with funding from the State of Maryland and the Maryland Cigarette Restitution Fund. The collection and availability of cancer registry data is also supported by the Cooperative Agreement NU58DP006333, funded by the Centers for Disease Control and Prevention. Its contents are solely the responsibility of the authors and do not necessarily represent the official views of the Centers for Disease Control and Prevention or the Department of Health and Human Services.

COLON: the authors would like to thank the COLON and NQplus investigators at Wageningen University & Research and the involved clinicians in the participating hospitals.

CORSA: We kindly thank all individuals who agreed to participate in the CORSA study. Furthermore, we thank all cooperating physicians and students and the Biobank Graz of the Medical University of Graz.

CPS-II: The authors express sincere appreciation to all Cancer Prevention Study-II participants, and to each member of the study and biospecimen management group. The authors would like to acknowledge the contribution to this study from central cancer registries supported through the Centers for Disease Control and Prevention's National Program of Cancer Registries and cancer registries supported by the National Cancer Institute's Surveillance Epidemiology and End Results Program. The authors assume full responsibility for all analyses and interpretation of results. The views expressed here are those of the authors and do not necessarily represent the American Cancer Society or the American Cancer Society – Cancer Action Network.

Czech Republic CCS: We are thankful to all clinicians in major hospitals in the Czech Republic, without whom the study would not be practicable. We are also sincerely grateful to all patients participating in this study.
DACHS: We thank all participants and cooperating clinicians, and everyone who provided excellent technical assistance.

EDRN: We acknowledge all contributors to the development of the resource at University of Pittsburgh School of Medicine, Department of Gastroenterology, Department of Pathology, Hepatology and Nutrition and Biomedical Informatics.

EPIC: Where authors are identified as personnel of the International Agency for Research on Cancer/World Health Organization, the authors alone are responsible for the views expressed in this article and they do not necessarily represent the decisions, policy or views of the International Agency for Research on Cancer/World Health Organization.

EPICOLON: We are sincerely grateful to all patients participating in this study who were recruited as part of the EPICOLON project. We acknowledge the Spanish National DNA Bank, Biobank of Hospital Clinic~IDIBAPS and Biobanco Vasco for the availability of the samples. The work was carried out (in part) at the Esther Koplowitz Centre, Barcelona.

Harvard cohorts: The study protocol was approved by the institutional review boards of the Brigham and Women’s Hospital and Harvard T.H. Chan School of Public Health, and those of participating registries as required. We acknowledge Channing Division of Network Medicine, Department of Medicine, Brigham and Women’s Hospital as home of the NHS. The authors would like to acknowledge the contribution to this study from central cancer registries supported through the Centers for Disease Control and Prevention’s National Program of Cancer Registries (NPCR) and/or the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) Program. Central registries may also be supported by state agencies, universities, and cancer centers. Participating central cancer registries include the following: Alabama, Alaska, Arizona, Arkansas, California, Colorado, Connecticut, Delaware, Florida, Georgia, Hawaii, Idaho, Indiana, Iowa, Kentucky, Louisiana, Massachusetts, Maine, Maryland, Michigan, Mississippi, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Carolina, North Dakota, Ohio, Oklahoma, Oregon, Pennsylvania, Puerto Rico, Rhode Island, Seattle SEER Registry, South Carolina,
Tennessee, Texas, Utah, Virginia, West Virginia, Wyoming. The authors assume full responsibility for analyses and interpretation of these data.

Kentucky: We would like to acknowledge the staff at the Kentucky Cancer Registry.

LCCS: We acknowledge the contributions of Jennifer Barrett, Robin Waxman, Gillian Smith and Emma Northwood in conducting this study.

NCCCS I & II: We would like to thank the study participants, and the NC Colorectal Cancer Study staff.

NSHDS investigators thank the Västerbotten Intervention Programme, the Northern Sweden MONICA study, the Biobank Research Unit at Umeå University and Biobanken Norr at Region Västerbotten for providing data and samples and acknowledge the contribution from Biobank Sweden, supported by the Swedish Research Council.

PLCO: The authors thank the PLCO Cancer Screening Trial screening center investigators and the staff from Information Management Services Inc and Westat Inc. Most importantly, we thank the study participants for their contributions that made this study possible.

Cancer incidence data have been provided by the District of Columbia Cancer Registry, Georgia Cancer Registry, Hawaii Cancer Registry, Minnesota Cancer Surveillance System, Missouri Cancer Registry, Nevada Central Cancer Registry, Pennsylvania Cancer Registry, Texas Cancer Registry, Virginia Cancer Registry, and Wisconsin Cancer Reporting System. All are supported in part by funds from the Center for Disease Control and Prevention, National Program for Central Registries, local states or by the National Cancer Institute, Surveillance, Epidemiology, and End Results program. The results reported here and the conclusions derived are the sole responsibility of the authors.

SEARCH: We thank the SEARCH team

SELECT: We thank the research and clinical staff at the sites that participated on SELECT study, without whom the trial would not have been successful. We are also grateful to the 35,533 dedicated men who participated in SELECT.
WHI: The authors thank the WHI investigators and staff for their dedication, and the study participants for making the program possible. A full listing of WHI investigators can be found at: http://www.whi.org/researchers/Documents%20Write%20a%20Paper/WHI%20Investigator%20Short%20List.pdf

Data availability statement

We obtained summary genetic association data on breast cancer risk from the Breast Cancer Association Consortium (https://bcac.ccge.medschl.cam.ac.uk/), ovarian cancer risk from the Ovarian Cancer Association Consortium (https://ocac.ccge.medschl.cam.ac.uk/), endometrial cancer risk from the Endometrial Cancer Association Consortium (https://www.ebi.ac.uk/gwas/publications/30093612#study_panel), non-Hodgkin lymphoma risk from Burrows et al. (10.5523/bris.aed0u12w0ede20olb0m77p4b9), and basal cell carcinoma risk from Adolphe et al (https://www.ebi.ac.uk/gwas/publications/33549134#study_panel). Approval was received to use restricted summary genetic association data from GECCO, INTEGRAL ILCCO, and PRACTICAL consortia after submitting a proposal to access this data. Summary genetic association data from these consortia can be accessed by contacting GECCO (kafdem@fredhutch.org), INTEGRAL ILCCO (rayjean.hung@lunenfeld.ca) (https://ilcco.iarc.fr/), and PRACTICAL (practical@icr.ac.uk). Approval was also received to use restricted summary genetic association data on pancreatic cancer risk via dbGaP release phs000206.v5.p3. To enquire about gaining access to summary genetic association data for renal and head and neck cancer risk, contact brennanp@iarc.fr. To enquire about gaining access to summary genetic association data for bladder cancer risk, contact bart.kiemeney@radboudumc.nl.

GWAS study selection

Study QC and pre-processing

Meta-analysis

Instrument construction

pQTL beta agreement

Validation analyses

Discovery analyses

Mendelian randomization analysis

Sensitivity analyses

eQTL enrichment and multi-trait colocalisation

Drug repurposing assessment

Identification of GWAS with measured circulating inflammatory markers

Map UniProt ID to platform-specific protein ID, drop problematic probes, extract cis-window for data extraction, drop SNPs with MAF < 0.01, drop palindromic SNPs with MAF > 0.40

Inverse-variance weighted fixed-effects meta-analysis in METAL

Extract SNPs at genome-wide significance ($P < 5.0 \times 10^{-8}$), drop SNPs with evidence of heterogeneity ($P_{het} < 0.001$), construct instruments permitting LD $r^2 < 0.10$ in PLINK

Check per-study beta agreement for each pQTL using independent ($r^2 < 0.01$) SNPs across two thresholds ($P < 5.0 \times 10^{-8}$, $P < 5.0 \times 10^{-4}$)

Test inflammatory marker-cancer pairs with Overall association score $\geq 0.05$ in Open Targets in Validation analyses. Test all remaining inflammatory marker-cancer pairs in Discovery analyses

Wald ratio or inverse-variance weighted random-effects model adjusted for LD between variants

Colocalisation, iterative leave-one-out analysis, evaluation and dropping of missense variants (or variants in high LD, $r^2 > 0.80$) with missense variants from instruments to prevent potential aptamer-binding effects

Examination of overlap of instruments with tissue-specific or immune cell-specific gene expression quantitative trait loci ($P < 5 \times 10^{-8}$), multi-trait colocalisation to evaluate shared aetiology across traits

Evaluation of approved, investigational, or experimental drugs targeting inflammatory markers in DrugBank to identify potential drug repurposing opportunities for cancer prevention
