Abstract: In a fraction of SARS-CoV-2 infected individuals treated with the oral antiviral Paxlovid, the virus rebounds following treatment. The mechanism driving rebound is not understood. Here, we show that viral dynamic models based on the hypothesis that Paxlovid treatment near the time of symptom onset halts the depletion of target cells, but may not fully eliminate the virus, which can lead to viral rebound. We also show that the occurrence of viral rebound is sensitive to model parameters, and the time treatment is initiated, which may explain why only a fraction of individuals develop viral rebound. Finally, the models are used to test the therapeutic effects of two alternative treatment schemes. These findings also provide a possible explanation for rebounds following other antiviral treatments for SARS-CoV-2.

Significance:
Paxlovid is an effective treatment for SARS-CoV-2. In some patients treated with Paxlovid, the initial reduction in viral load is followed by a rebound once treatment is stopped. Understanding the mechanisms of the rebound may help us develop better treatment strategies to minimize this
possibility. We hypothesize that early treatment with Paxlovid stops viral growth, but may not fully clear the virus, thus preserving host resources that would have otherwise been used by the virus. Once treatment ends, the remaining viruses can utilize the available resources to grow, leading to the observed transient viral rebound. We built standard viral dynamic models based on this hypothesis and fit the models to data to show its feasibility. We further examined the effect of two alternative treatment schemes.

**Introduction**

A 5-day course of Paxlovid is recommended for individuals who tested positive for SARS-CoV-2 with mild to moderate symptoms and a high risk of progression to severe disease (1, 2). Treatment is suggested to be initiated as soon as possible and within 5 days of symptom onset, with two doses per day. A dose of Paxlovid consists of 300 mg nirmatrelvir and 100 mg of ritonavir, where nirmatrelvir is a protease inhibitor that blocks SARS-CoV-2 replication and ritonavir reduces the liver catabolism of nirmatrelvir and thus prolongs its half-life (1). While Paxlovid substantially reduces the risk of progression to severe COVID-19 and can shorten the duration of infectiousness in high-risk individuals (2-5), in some cases viral rebound and recurring symptoms occur after the 5-day treatment, including in individuals who have been vaccinated and/or boosted. Symptoms resolve within a median of 3 days after rebound without additional intervention (6). Some individuals with viral rebound are reported to have culturable virus up to 16 days after the initial diagnosis (7) and it is possible that transmission to close contacts may occur during the rebound period (8). Furthermore, viral rebound does not appear to be caused by the emergence of drug resistant mutants (8-10).

The fraction of individuals treated with Paxlovid that exhibit viral rebound has not been well quantified, and estimates vary. For example, in a cohort of 484 high-risk individuals treated with Paxlovid, four individuals (0.8%) experienced rebound of symptoms (11). In the phase 3
Paxlovid clinical trial, EPIC-HR, the fraction of individuals with viral rebound (positive PCR test) and recurring symptom was 1-2% (2). A recent study at the Beth Israel Deaconess Medical Center reported 3 out of 11 mRNA vaccinated individuals who were treated with Paxlovid developed rebound (27% vs. 4% in an untreated group) (12). In a retrospective study of electronic health records of 11,270 patients aged 18 years or older that contracted COVID-19 between 1/1/2022 and 6/8/2022 and were treated with Paxlovid, 3.53% exhibited rebound between 2 and 7 days after treatment (13).

In this study, we analyze the data presented in Charness et al. (8), where quantitative PCR data is available for three individuals who experienced viral and symptom rebounds after taking Paxlovid. In all three individuals, no mutations occurred during treatment in the gene encoding the protease targeted by nirmatrelvir and there was no evidence of reinfection by a different variant (8). This is like other studies reporting no detectable mutations in Paxlovid-treated rebound individuals (7, 10). We show that viral dynamic models explain the rebound phenomenon, based on the idea that 5-day Paxlovid treatment started near the time of symptom onset reduces the depletion of target cells but does not fully eliminate virus, thus allowing the virus to rebound once treatment is stopped. Further, we show that such models generate viral dynamic profiles that agree with the data. We also show that the occurrence of viral rebound is sensitive to model parameters and the time therapy is started so that one would expect only a minority of treated individuals to rebound. Lastly, we use our model to examine the potential effects of giving Paxlovid for 10 days or a second course of Paxlovid after symptoms return. While we use Paxlovid as a case study, our theory also can also explain the viral rebound observed after treatment with molnupiravir (13), the only other oral antiviral with emergency use authorization.
Results

The viral dynamic model matches the viral rebound observed in patient data

Our viral dynamic model (see Methods) can describe the observed data including the viral rebound in the three treated individuals (Fig. 1). We observe that after treatment starts, the decline in target cells is temporarily halted (Fig. 1), which indicates Paxlovid preserves target cells. The remaining target cells can support viral replication if there is viable virus remaining after treatment ends. Note that in patient 1 the virus rebounds to a very high level which depletes the remaining target cells. Due to this there was no support for including an adaptive immune response in the model for this patient. In the other two patients, ultimate clearance of the virus was due to an adaptive immune response developing at time $t^*$ specified in the figure caption.

Fig. 1. Best fit of the viral dynamic model (solid curves) to the viral load data (open circles). The shaded area is the duration of treatment. The dashed curve is the model predicted fraction of target cells remaining. The following parameter were fixed for all three patients at values previously determined in the literature (14): $k = 4 \text{ day}^{-1}$, $\delta = 1.7 \text{ day}^{-1}$, $c = 10 \text{ day}^{-1}$.

Additionally, fitting indicated for patient 1, $\beta = 2.32 \times 10^{-9} \text{ mL RNA copies}^{-1} \text{day}^{-1}$, $\pi = 1.77 \times 10^3 \text{ RNA copies mL}^{-1} \text{day}^{-1}$, and treatment was from day 3 to day 8. For patient 2, $\beta = 1.54 \times 10^{-9} \text{ mL RNA copies}^{-1} \text{day}^{-1}$, $\pi = 1.47 \times 10^3 \text{ RNA copies mL}^{-1} \text{day}^{-1}$, $t^*$ =
9.1 days, $\sigma = 0.82 \text{ day}^{-1}$ and treatment was from day 3.5 to day 8.5. For patient 3, $\beta = 8.24 \times 10^{-10} \text{ mL RNA copies}^{-1} \text{ day}^{-1}$, $\pi = 1.89 \times 10^3 \text{ RNA copies mL}^{-1} \text{ day}^{-1}$, $t^* = 12.0 \text{ days}$, $\sigma = 1.22 \text{ day}^{-1}$ and treatment was from day 5 to day 10.

*The effects of two hypothetical alternative Paxlovid treatment schedules.*

Although extending the treatment duration of Paxlovid is not currently recommended as the vast majority of treated individuals do not rebound, it is still of interest to see what our model predicts if we extend the treatment duration by either having one continuous 10-day treatment or start an additional 5-day treatment one day after symptoms rebounded. The times symptoms returned were 5, 5 and 3 days after treatment ended for patients 1, 2, and 3, respectively (8).
By extending the treatment duration, it is possible to prevent viral rebound in patients 2 and 3 (Fig. 2A). However, for patient 1, viral rebound is predicted to still occur after the end of treatment as the viral load and number of infected cells were not driven to extinction. For patients 2 and 3 adaptive immunity starting between days 9 and 12, as predicted in Fig. 1, was needed to explain the observed data and in the model simulations drove the viral load to undetectable levels before the extended duration treatment ended. On the other hand, adding a second course of treatment one day after symptoms returned is predicted to have minimal impact.

**Fig. 2.** Model simulation with a 10-day hypothetical treatment: (A) 10 consecutive days treatment (B) a second Paxlovid course started one day after symptoms returned. Solid red curves are the model predicted viral load using the parameters given in the Fig. 1 caption. The dashed blue curve is the model predicted number of target cells under the hypothetical treatment. The solid blue curves in (B) are the predicted viral trajectory with the standard five-day course of Paxlovid reproduced from Fig. 1. The shaded area is the duration of treatment.
on the viral trajectory toward clearance compared to a single course of treatment especially for patients 1 and 2 (Fig. 2B).

The sensitivity of viral rebound to treatment initiation time and patient specific parameters

We used simulation experiments to show that delaying treatment with Paxlovid can decrease the probability of rebound in general. We first generated an in silico cohort of SARS-CoV-2 patients as described in the Supplementary text. We then simulated a trial with 100 in silico treated patients and assessed what percentage exhibited rebound, which was defined as the viral load returning above $10^5$ RNA copies per mL. The rationale for $10^5$ RNA copies per mL is that above this value infectious cultures can often be obtained, indicating the possibility of transmission. We repeated this trial protocol 20 times each for treatment starting at days 2, 3, 4 and 5. In Fig. 3A, we present boxplots of the percentage of rebound patients obtained from these 20 trials. Examples of 100 viral trajectories for each treatment initiation time are provided in Fig. 3B. Based on these in silico trial results, the model predicts the probability of rebound decreases quickly with increasing delay in Paxlovid initiation. We also obtained a similar conclusion for the second model we developed that included an innate immune response (see Methods), see Fig. S9 in the Supplementary Materials.
Fig. 3. Percentage of predicted in silico patients with rebound relative to the time of treatment initiation. (A) Boxplots of the percentage of rebound cases from 20 trials with 100 virtual patients each for a different treatment initiation time. (B) Examples of 100 viral trajectories. Note the decreasing number of rebound cases as treatment starts later. The horizontal blue dashed line is the viral load threshold used to define rebound.

Another factor that may affect the level of target cells at the end of treatment are viral dynamic parameters: the infection rate $\beta$, the viral production rate $\pi$, and the viral clearance rate $c$. In Fig. 4, we simulate our viral dynamic model with parameters for patient 1, the patient with the most data, but varying values for $\beta$, $\pi$ or $c$. When either the infection rate or the viral production rate is higher by 15%, virus grows faster, leading to a faster reduction in the available target cells and no rebound. The same occurs if the viral clearance rate is reduced by ~20%. At the end of treatment, less than 1.8% of target cells remain with an increased value of either $\beta$ or $\pi$ by 15% or a decrease in $c$ by 20% versus 24.4% remaining with the baseline parameters (Figs. 1 and 2). We further generalized the effect of varying the viral dynamics parameters on rebound.
using the in silico patients (Fig. S7, Supplementary Materials). Altogether, we showed that differences among treated individuals in viral dynamic parameters may explain why some individuals may be more likely to experience rebound than others.

![Model simulation with variation in values of $\beta$, $\pi$ and $c$ for patient 1.](image)

**Fig. 4.** Model simulation with variation in values of $\beta$, $\pi$ and $c$ for patient 1. Solid red curves are the model simulated viral load. The dashed blue curve is the number of target cells. The shaded area is the duration of treatment. In the panels from left to right, the model is simulated with $\beta$ 15% higher, $\pi$ 15% higher, and $c$ 20% lower than in the best-fit in Fig. 1 for patient 1.

**Discussion**

In this study, we used a well-established viral dynamic model to show that early treatment with Paxlovid may preserve target cells which can then lead to viral rebound after the end of treatment. Additionally, the precise time therapy is initiated, within-host viral dynamic parameters, an individuals’ specific response to Paxlovid (e.g., variation in pharmacokinetic and pharmacodynamics parameters– not shown), and the timing of adaptive immunity play important roles in determining whether viral rebound occurs. These important factors vary from individual to individual and may explain why only some individuals show viral rebound after completing treatment with Paxlovid.
Using parameter values within the range of literature values (see Supplementary Materials), we showed that a standard viral dynamic model without an adaptive immune response can capture the viral load changes observed in patient 1 including viral rebound and clearance (Fig. 1). We then showed that the model can also describe the viral load data in patients 2 and 3 when the effect of adaptive immunity is added to the model (Fig. 1).

Interestingly, the three patients studied here were all vaccinated and boosted and nonetheless had breakthrough infections with Omicron subvariant BA1.20 (patient 1) or BA2.9 (patients 2 and 3) (8). Thus, while adaptive immune responses may have occurred, they were either too weak or too late to prevent infection. In fact, our model suggests that in patient 1 the response even after breakthrough infection continued to be too weak or too late to affect the observed viral dynamics, i.e., the predicted time for the onset of the response $t^*$ is past the last data point at day 21. One could speculate that an adaptive response occurred and preserved additional target cells but there is no data to support this speculation. For this reason, we chose not to include adaptive immunity for patient 1.

The viral dynamics observed in patients 1-3 can be captured equally well by an immune response (IR) model, where the protective effects of innate immunity can preserve target cells by putting them into an antiviral state (see Supplementary Materials). Again, for patient 1 there is no support for including an adaptive response. From a biological perspective the IR model is attractive but it introduces additional parameters, which are difficult to estimate due to the lack of quantitative data about the innate response in these viral rebounders.

Shortly after treatment begins, Paxlovid reduces viral production, which halts the decline in target cells. This preservation effect leaves target cells at an approximately constant level over the course of treatment. Once the 5-day course of treatment is complete, if the level of preserved
target cells is sufficient, it can allow the virus to rebound. Through simulations, we showed that there are three key factors that determines whether the level of preserved target cells after the completion of a 5-day treatment with Paxlovid is sufficient to support viral rebound.

First, the timing of treatment plays a crucial role. If treatment is initiated too early, before a time we denote $t_{critical}$, a substantial number of target cells remains after the 5-day treatment and viral rebound is likely to occur (Fig. 1). After $t_{critical}$ too few target cells remain to support viral growth. Since viral growth switches to viral decay at the time of the viral peak in an untreated individual, this means $t_{critical}$ is the time the viral peak is reached. In more technical terms $t_{critical}$ corresponds to the time the reproductive number $R = 1$, so that on average each infected cells infects exactly one other cell, so that there is neither growth nor decay in the number of infected cells and level of viremia. According to a human challenge study (15), $t_{critical}$ should be ~ 5 days after infection, or about 1 to 3 days after symptom onset. This suggests that delaying treatment may be a strategy to reduce the possibility of viral rebound. However, Paxlovid treatment accelerates viral clearance and hence potentially can reduce viral transmission. Thus, delaying treatment may have a detrimental effect on public health and deserves more study. In addition, delaying treatment could also have impact on the severity of disease in the high-risk patients for whom Paxlovid is recommended.

All viral dynamic parameters affect $R$ and hence they affect $t_{critical}$. Due to the differences in viral dynamic parameters from patient to patient, $t_{critical}$ is different for each patient, which means the best time to start treatment to obtain both a rapid viral decline and prevent viral rebound is likely to be different for each patient. However, in general, delaying treatment may decrease the probability of developing rebound (Figs. 3).
While adaptive B and T cell immune responses may have occurred too late to prevent infection, they could still have affected the level of preserved target cells. Thus, their timing and emergent speed may play a crucial role in the occurrence of viral rebound. Early treatment with Paxlovid reduces the viral load and number of infected cells, which may delay both the innate and adaptive immune responses and so may also contribute to the observed viral rebound.

In summary, our model suggests the occurrence of viral rebound following a complete course of Paxlovid may be due to incomplete virus clearance and the level of preserved target cells. Increasing the length of treatment from 5 to 10 days will continue to preserve target cells and thus may still allow viral rebound if viable virus is present at the end of treatment and sufficient adaptive immunity has not developed. Furthermore, starting an additional course of treatment one day after symptom rebound makes little difference in the viral clearance time. However, delaying initiation of treatment for a day or two after having symptoms or testing positive may have some benefit in reducing the possibility of rebound, but at the cost of allowing viral growth to continue and the possibility of increased viral transmission and detrimental effects on the course of disease severity. Clinical trials could evaluate these various potential treatment strategies. Lastly, rebound following antiviral treatments is not unique to Paxlovid (13). These findings may provide an explanation to rebound following other antiviral treatments besides Paxlovid.

Methods

We use two models to study viral rebound, a standard viral dynamic model related to the one developed by Baccam et al. (16) to study acute influenza infections and an expanded version of that model that includes an innate response involving type I interferon (IFN), called the IR model. Both models make very similar predictions. Thus, we present the simpler model without
an innate response in the main text while the model with IFN is discussed in the Supplementary Materials.

The model we use is described by the following set of ordinary differential equations:

\[
\frac{dT}{dt} = -\beta VT
\]
\[
\frac{dE}{dt} = \beta VT - kE
\]
\[
\frac{dI}{dt} = kE - \delta(t)I
\]
\[
\frac{dV}{dt} = (1 - \epsilon(C))\pi I - cV.
\]

In this model, \(T\) is the number of target cells, \(E\) is the number of infected cells that have not yet started to produce virus, i.e., are in the eclipse phase, \(I\) is the number of productively infected cells, and \(V\) is the viral load. Target cells become infected with rate constant \(\beta\). After being infected for an average time of \(1/k\), infected cells start producing virus at an adjusted rate \(\pi\) that accounts for sampling via a swab (14) and die at per capita rate \(\delta\), which we allow to be time dependent as described below. SARS-CoV-2 viruses are cleared at per capita rate \(c\). The effectiveness of nirmatrelvir in blocking viral replication and subsequent production of virions is given by \(\epsilon(C) = \epsilon_{max} \frac{C}{C + EC_{50}}\), an \(E_{max}\) model where \(C\) is the concentration of nirmatrelvir, \(EC_{50}\) is the concentration at which the drug effectiveness is half-maximal and \(\epsilon_{max}\) is the maximum effectiveness. When \(\epsilon(C) = 0\) the drug has no effect and when \(\epsilon(C) = 1\) the drug is 100% effective at blocking virion production.

We include in this model (and the IR model in the Supplementary Materials) a possible adaptive immune response, since rebounds tend to occur late after infection, when the adaptive immune response is expected to be important. As in a previous study by Pawelek et al. (17), we added this response to the model starting at time \(t^{*}\). We assume that the adaptive response
increases exponentially at rate $\sigma$ and causes an increase in the death rate of infected cells. This increased death rate could be due to the increasing presence of cytotoxic T cells or of viral-specific antibodies that bind to infected cells and cause their death by processes such as antibody-dependent cytotoxicity, antibody-dependent phagocytosis or complement-mediated death. To account for these phenomena, we use the following time-dependent infected cell death rate $\delta(t)$:

$$
\delta(t) = \begin{cases} 
\delta_0 & \text{for } t < t^* \\
\delta_0 e^{\sigma(t-t^*)} & \text{for } t \geq t^*
\end{cases}
$$

As it is impossible to know the number of viruses that initiated infection, we use a method suggested by Smith et al. (18) in which we assume the initiating virus is either cleared or rapidly infects cells. Thus, as initial conditions we use: $T(0) = 8 \times 10^7$ cells, $E(0) = 1$ cell, $I(0) = 0, V(0) = 0$, and $R(0) = 0$ as explained in Ke et al. (14). We note that the infection dynamics are relatively insensitive to increasing the initial number of infected cells to 10 (14).

**Pharmacokinetic model for Paxlovid**

We assume the drug effectiveness $\epsilon(C)$ depends on the concentration of nirmatrelvir, $C(t)$, according to an $E_{\text{max}}$ model with EC50 = 62 nM (1). Following a *single dose* of nirmatrelvir of 300 mg with 100 mg of ritonavir, the observed maximum nirmatrelvir concentration is $C_{\text{max}} = 2.21 \frac{\mu g}{mL}$ (1). As nirmatrelvir has a molecular weight of 499.54 $\frac{g}{mol}$ (19) this value of $C_{\text{max}}$ can also be expressed as $4.4 \times 10^3$ nM. The half-life of nirmatrelvir when taken with ritonavir is about 6 hours (1), which corresponds to an elimination rate of 2.8/day. Additionally, dosing twice-daily achieved steady-state on day 2 with approximately 2-fold accumulation (1). Using a simple multidose absorption-elimination model, the pharmacokinetics of nirmatrelvir is given by (20)
\[ C(t) = \hat{C} \frac{k_a}{k_e - k_a} \left( \frac{e^{-k_e t}}{e^{k_a I_d} - 1} \right) \]

\[ \left[ 1 - e^{(k_e - k_a)t}(1 - e^{N_d k_a I_d}) + (e^{k_e I_d} - e^{k_a I_d}) \left( \frac{e^{(N_d-1)k_e I_d} - 1}{e^{k_e I_d} - 1} \right) - e^{((N_d-1)k_e+k_a)I_d} \right]. \]

Here, \( k_e \) is the elimination rate (2.8/day), \( k_a \) is the absorption rate (17.5/day), \( I_d \) is the dosing interval (1/2 day), \( N_d = \text{integer} \left( \frac{t}{I_d} \right) + 1 \) is the number of doses until time \( t \), with the first dose at time \( t = 0 \). \( \hat{C} = \frac{FD}{V_d} = (6.25 \times 10^3 nM) \), where \( F \) is the bioavailability of the drug, \( D \) is the mass of the drug administered in a dose (300 mg), and \( V_d \) is the volume of distribution. Details on the implementation of the pharmacokinetic model and the parameter values used can be found in the Supplemental Material. With these assumptions, the drug effectiveness \( \epsilon(C) \) hovers around 0.98 during treatment (Fig. S1) and then falls to zero rapidly after treatment stops (Fig. S2).

**Data fitting**

For comparison between our model and data, we converted the PCR cycle threshold (Ct) values reported in Charness et al. (8) to log\(_{10}\) RNA copies (see Supplemental Material). Viral load data for patients 2 and 3, using a different PCR system, were kindly provided by David Ho (Supplemental Material). The duration from the time of infection to symptom onset is assumed to be 3 days for all three patients, which is midway between the 2-4 days reported in a human challenge study (15). The time after symptom onset when treatment started is reported in Charness et al. (8), as day 0, day 1, and day 2 for patients, 1, 2 and 3 respectively, but for patient two we used 12 hours, which is more accurate as reported in (21).
We fit the model to viral load data using the optimization function `fminsearch` (MATLAB 2021b), which uses the Nelder-Mead simplex direct search method, to minimize the difference:

\[
SQE = \sum_{t_d} \left( \log_{10} V(t_d) - \log_{10}(V_{t_d}) \right)^2.
\]

Here, \( t_d \) is the time that corresponds to the available data \( V_{t_d} \).
