Abstract

In the present study, we report on mosaic variegated aneuploidy (MVA) syndrome with tetraploidy and predisposition to infertility in a family. Sequencing analysis identified that the CEP192 biallelic variants (c.1912C>T/p.H638Y and c.5750A>G/p.N1917S) segregated with microcephaly, short stature, limb–extremity dysplasia, and reduced testicular size, while CEP192 monoallelic variants segregated with infertility and/or reduced testicular size in the family. In 1,264 unrelated patients, variant screening for CEP192 identified a same variant (c.5750A>G/p.N1917S) and other variants significantly associated with infertility. Two lines of Cep192 mice model that are equivalent to human variants were generated. Embryos with Cep192-biallelic variants arrested at E7 because of cell apoptosis mediated by MVA/tetraploidy cells’ acumination. Mice with heterozygous variants replicated the predisposition to male infertility. Mouse primary embryonic fibroblasts with Cep192-biallelic variants cultured in vitro showed abnormal morphology, mitotic All rights reserved. No reuse allowed without permission.
arresting, and disruption of spindle-formation. In patient epithelial cells with biallelic variants cultured in vitro, the number of cells arrested during the prophase increased because of the failure of spindle formation. Accordingly, we present a novel disease gene *CEP192*, which as a link for the MVA syndrome with tetraploidy and the predisposition to male infertility.

Mosaic variegated aneuploidy syndrome with tetraploidy, and predisposition to male infertility triggered by mutant *CEP192*

In the present study, we report on mosaic variegated aneuploidy (MVA) syndrome with tetraploidy and predisposition to infertility in a family. Sequencing analysis identified that the *CEP192* biallelic variants (c.1912C>T/p.H638Y and c.5750A>G/p.N1917S) segregated with microcephaly, short stature, limb–extremity dysplasia, and reduced testicular size, while *CEP192* monoallelic variants segregated with infertility and/or reduced testicular size in the family. In 1,264 unrelated patients, variant screening for *CEP192* identified a same variant (c.5750A>G/p.N1917S) and other variants significantly associated with infertility. Two lines of *Cep192* mice model that are equivalent to human variants were generated. Embryos with *Cep192*-biallelic variants arrested at E7 because of cell apoptosis mediated by MVA/tetraploidy cells’ acumination. Mice with heterozygous variants replicated the predisposition to male infertility. Mouse primary embryonic fibroblasts with *Cep192*-biallelic variants cultured in vitro showed abnormal morphology, mitotic arresting, and disruption of spindle-formation. In patient epithelial cells with biallelic variants cultured in vitro, the number of cells arrested during the prophase increased because of the failure of spindle formation. Accordingly, we present a novel disease gene *CEP192*, which as a link for the MVA syndrome with tetraploidy and the predisposition to male infertility.

Mosaic variegated aneuploidy, Tetraploidy, Male infertility, *CEP192* mutation
Introduction

Correct cell division requires chromosomal duplication and separation into two daughter cells. Errors in this process may result in multipoidy, haploid, or aneuploidy, which causes human diseases. Mosaic variegated aneuploidy (MVA) syndrome is a rare disorder, in which one-quarter or more of cells in affected individuals have an abnormal number of chromosomes [ref1-2]. Individuals with MVA syndrome exhibit microcephaly, developmental delay, and other variable abnormalities such as increased risk to malignancies and Dandy–Walker malformation [ref2]. From literatures, several patients with MVA syndrome have been reported [ref 1-7]; three disease genes have been identified for MVA syndrome, including BUB1B (OMIM:257300) [ref1], CEP57 (OMIM: 614114) [ref6], and TRIP13 (OMIM: 617598) [ref7]. Tetraploidy is another error in chromosome separation, and it refers to the presence of four copies of the genome in a cell [ref8]. In human, tetraploidy has been described frequently in spontaneous abortions [ref9] and in tumorigenesis [ref8, 10]. Genetic instability such as MVA is usually preceded by tetraploidy during tumor revolution [ref 9, 10-12]. In early time, errors in chromosome segregation have also been reported in male subfertility [ref15-16]. Variants on a centrosome gene PLK4, which control spindle formation and chromosome separation, has been recently reported on aneuploidy and male infertility [ref 17-20]. Nevertheless, the key molecule that drives the formation of tetraploidy is unknown; not all patients with MVA syndrome can be explained by known MVA genes, and no evidence of a molecule that link the MVA, tetraploidy, and infertility together has been reported. In this study, we report on an interesting family with two siblings suffered by MVA syndrome with tetraploidy, and other two members suffered by reduced testicular size and infertility. We exemplify a novel gene CEP192 biallelic variants lead to the MVA syndrome plus tetraploidy, and CEP192 monoallelic variants lead to predisposition to male infertility by a series of experiments performed on human subjects and mice models with equivalent variants.
Results

A family with unexplained diseases

Two siblings (patient A and patient B) that experienced microcephaly, developmental delay, limb–extremity dysplasia, facial abnormalities, and reduced testis size came to our clinic for genetic counselling (Table 1, Supplementary Methods). Genetic investigation showed that two other family members (patient C and patient D) suffered from reduced testicular volume (Supplementary Table 1), and patient D was completely infertile. Semen analysis on patient D revealed severe oligozoospermia (Supplementary Table 1). Testicular biopsy revealed a comprehensive reduction of germ cells in his available seminiferous tubules without spermatozoa (Figure 1). Similar semen parameters were observed on patient C (Supplementary Table 1). GTG-banding on patient A and B revealed that 15.52%–24.14% of lymphocytes were tetraploidy cells, 26.44%–27.27% were MVA cells, and 7%–12.33% of metaphase cells showing premature sister chromatid separation (PSCS, Figure 2, Table 1, Supplementary Figure 1, Supplementary Methods). In addition, a lower but substantial proportion of MVA/tetraploidy cells was observed on patient C and patient D (Table 1, Supplementary Methods).

According to diagnostic criteria (a quarter or more cells were MVA) [ref1-2], and patient A and patient B fulfilled the diagnosis of MVA syndrome. Considering that, in addition to MVA, patient A and patient B also had tetraploidy, and tetraploidy has never been described in patients with MVA syndrome. Accordingly, we proposed a subtype of MVA syndrome, namely, the MVA syndrome with tetraploidy, for the siblings. To search for the cause for the family, we performed variant screening for known MVA syndrome genes (e.g., BUB1B, CEP57, and TRIP13) [ref 1, 6-7], but no causative variant was identified.

Identification of CEP192 variants

Exome sequencing (ES) was successfully performed for patient A, patient B and their parents (Supplementary Table 2). Considering that MVA syndrome is a rare, autosomal recessive disorder [ref 1, 6-7], we focused on genes with rare bi-allelic variants on patient A and patient B according to reasonable filtering strategy (Supplementary Figure 2). Only two compound heterozygous
variants of \textit{CEP192} (NM\_032142.4; c.1912C>T/p. H638Y and c.5750A>G/p.N1917S) met the filtering criteria. Sanger sequencing identified the \textit{CEP192} biallelic variants were co-segregated with syndromic phenotypes on patient A and patient B, and the \textit{CEP192} monoallelic variant was co-segregated with reduced testicular-size/infertility on patient C and patient D (Figure 1A).

\textbf{CEP192 associated with male infertility in general population}

We determined whether \textit{CEP192} variants were involved in male infertility in general population. Variant screening of the \textit{CEP192} coding regions was performed for 1,264 unrelated males with idiopathic infertility. By focusing on rare variants (MaF<0.001 in Eas\_gnomAD), dozens of variants were retained. The p.N1917S variant of \textit{CEP192} was recurrently detected in three unrelated infertile males with reduced testicular volumes (patient E, F and G; Table 1). In addition, other variants on \textit{CEP192} were repeatedly detected in infertile males (Supplementary Table 3–5). Clinical reevaluation confirmed that all three males with p.N1917S variant were infertile, and GTG-band results revealed that a substantial part of the cells was MVA/tetraploidy (Table 1, Supplementary Method).

\textbf{Evolutionary conservation of p.N1917, and abnormal splicing of c.1912C>T}

\textit{CEP192} is a 2,537 residue-long protein with eight tandem domains in its C-terminal part that are similar to members of the PapD-like superfamily [ref 21]. Tandem domains 4 and 5 of human \textit{CEP192} constitute the Spd2 domain, which is ubiquitously present in all SPD2/CEP192 homologs and represents the most conserved region among the protein [ref 21-22]. The p.N1917S variant is located in the tandem domain 5 (Figure 3A). However, the other variant, namely, the c.1912C>T/p. H638Y, is located on the N-terminal, which is not conserved among different species (Figure 3A). The “Y” amino acid can be seen in residue 638 in \textit{Nannospalax galili} (Figure 3A). However, programs in silico prediction [ref 23-24] estimated the c.1912C>T variant affects normal splicing by disrupting Exon 14-donor splice site. Total RNA was then extracted from patient cells, and a complementary strand of DNA (cDNA) was generated. qPCR assay showed that \textit{CEP192} cDNA was considerable reduced in cases with c.1912C>T compared with that without the c.1912C>T variant (Figure 3B). The \textit{CEP192} transcript at the mRNA level was assessed by next-generation sequencing on a member with heterozygous c.1912C>T variant. Results showed that the c.1912T transcripts were detected in approximately 1% of the overall reads (Figure 3C). Furthermore, mini-gene assay showed that c.1912C>T led to the skipping of
exon 14 (Figure 3D), resulting in a frame shift and a premature termination codon (p.P604E*2). Thus, the functional mechanism of c.1912C>T should be the vast majority of mutant transcripts undergoing abnormal splicing, and the shortened transcripts mediated nonsense-mediated mRNA decay.

**Animal models confirmed that both CEP192 variants are pathogenic**

Two lines of Cep192-edited mice were generated consisting of a knock-in mice (Cep192<sup>+</sup>M) with a variant equivalent to human N1917S and a knock-out mice (Cep192<sup>−/−</sup>) mimicking the haploinsufficiency effect of the human c.1912C>T splicing variant (Supplementary Figures 3–4). In progeny derived from the crosses between two Cep192<sup>−/−</sup> mice, the ratio of Cep192<sup>−/+</sup> to heterozygote (Cep192<sup>+/+</sup>) was close to 1:2 (34 litters, 131 offspring calculated, Cep192<sup>−/+</sup>=52, Cep192<sup>+/+</sup>=79). No Cep192<sup>−/−</sup> offspring was obtained (Figure 4A, Supplementary Table 6), suggesting embryonic lethality in the Cep192<sup>−/−</sup> state. In parallel, in the progeny derived from the crosses between two Cep192<sup>+/M</sup> mice, the ratio of Cep192<sup>+/+</sup> progeny to Cep192<sup>−/+</sup> was close to 1:2 (21 litters, 158 offspring calculated, Cep192<sup>+/+</sup>=64, Cep192<sup>−/+</sup>=94). No Cep192<sup>M/M</sup> offspring was obtained (Figure 4A, Supplementary Table 7). Subsequently, Cep192<sup>+/M</sup> mice were bred with Cep192<sup>−/+</sup> mice to further verify the causality of both variants. The Cep192<sup>−/+</sup>, Cep192<sup>+/+</sup>, and Cep192<sup>M/M</sup> progeny can be survivable. However, no Cep192<sup>M/M</sup> mice were obtained (Figure 4A, Supplementary Table 8). The results above implicated that both the knock-out and the N1917S allele were causative agents.

**Mutant mice replicated MVA and tetraploidy phenotypes**

In vitro fertilization was performed. Cep192 homozygous mutant embryos could develop into blastocysts in vitro (Supplementary Figure 5). To explore the stage(s) in which the homozygous embryos undergo arrestation, we sacrificed pregnant mice at various days post coitum. Embryos were dissected at various developmental stages. Cep192<sup>−/−</sup> embryos appeared morphologically normal at E7 compared with their Cep192<sup>−/+</sup> or Cep192<sup>+/+</sup> littermates (Supplementary Figure 6). Embryonic death was detected for Cep192<sup>M/M</sup> embryos at E10, the size of dead embryos is equivalent to that in E7 (Figure 4B). The same results were observed on Cep192<sup>−/+</sup> embryos (Supplementary Figure 7). Embryos were dissected and ground to cell suspensions. Fluorescence in situ hybridization (FISH) showed a significant increase of MVA and tetraploidy cells in Cep192<sup>M/M</sup> embryo cells (Figure 4C). TUNNEL assay revealed that the number of apoptotic cells increased in Cep192<sup>M/M</sup> embryos compared with that of Cep192<sup>−/+</sup> embryos (Figure 4D). Similar
results were obtained in cell samples from Cep192−/− embryos (data not shown).

In addition, when Cep192+/− or Cep192+/M males were mated with wild type (WT) females, approximately 10% of the mated females experienced dystocia. The uteri of females with dystocia were dissected. Fetuses arrested in about E13-14 were observed; all arresting fetuses were heterozygous (23 tested, 10 were Cep192+/−; 13 were Cep192+/M) (Supplementary Figure 8). Similar to Cep192−/− or Cep192M/M dead embryos, a remarkable proportion of cells (from the Cep192+/− or Cep192+/M arrested embryos) were MVA or tetraploidy (Supplementary Figure 9). TUNNEL assay also revealed that up to 40%–50% of the cells from the Cep192+/M that arrested embryos underwent apoptosis (Supplementary Figure 9).

Male mice with Cep192 heterozygous variants replicated infertility

Breeding assays were performed to check the reproductive capability of male mice with Cep192 heterozygous variants. Cep192+/− males were mated with WT females from complete sexual maturity (2 months) to 9 months. In comparison with WT males mated with WT females with average number of litters of 6.6, the Cep192+/− or Cep192+/M males mated to WT females exhibited reproductive defects with phenotypic variation among individuals (Figure 5; Supplementary Table 9-11). The number of litters or pups was reduced considerably in Cep192+/− or Cep192+/M males when they mated with WT females (Figure 5AB; Supplementary Tables 9–11). Histological analysis was performed. In the majority of the fertile heterozygotes, testicular size and histology appeared normal. However, the testes of the infertile Cep192+/− or Cep192+/M males were smaller than those of the Cep192+/+ littermates (Figures 5CD, Supplementary Table 12). H&E staining revealed that in comparison with a large number of sperms shown in the epididymides of Cep192+/+ males, the epididymides of the infertile heterozygous mice were nearly empty (Figure 5 E). Meanwhile, in comparison with Cep192+/+ littermates, a substantial reduction of germ cells was observed in the seminiferous tubules of infertile Cep192+/− or Cep192+/M males (Figure 5 E).

Spindle formation was disrupted in CEP192-mutant cells

Mice embryo cells were cultured in vitro. Only a few Cep192−/− or Cep192M/M cells can adhere to disk walls (less than 1% vs. Cep192+/+ 60%). For the cells that can adhere, the cell division was very slow (almost cannot divide). As shown in cells in the interphase, the mutant cells exhibited bipolarized (or dysmorphic) cell shape (Figure 6). In comparison with Cep192+/− cells, an appropriate number of microtubules (MTs) were arranged in an orderly manner around the
centrosome, the $Cep192^{+/-}$ or $Cep192^{MM}$ cells exhibited decreased volume of MTs, and the MTs were disorganized (Figure 6AB). Some of the mutant cells seems lacking microtubule organizing center (MTOC, Figure 6AB). In several cells likely in mitosis, chromosomes arranged around lacking a spindle formation (Figure 6B). The investigation was focused on human cells with $CEP192$ variants to check the spindle status in mitotic cells. Epithelial cells (from patient B) were cultured in vitro. In the prophase, the nucleation of MTs occurred randomly, leading to disorganized, non-bipolar structures of spindle (Figure 7). Quantitative analysis was performed and indicated that the $CEP192$-mutated cells exhibited an increased proportion of mitotic cells in prophase (81.90% vs. 20.38% in control cells, Figure 7EF). We propose here that cells lacking normal spindle structure have high probability to be developed to the MVA or tetraploidy cells.

**DISUSSION**

In present study, we have investigated a family (F1) with two siblings that suffered from developmental delay, microcephaly, limb extremities malformation, and reduced testicular size. In addition, two other male family members showed reduced testicular size/infertility. Genetic inheritance was initially unknown for the family. The performance of GTG-banding identified MVA and tetraploidy cells in the patients. ES and further validation disclosed that $CEP192$ biallelic variants associated with the MVA syndrome with tetraploidy, and the $CEP192$ mono-allelic variants associated with reduced testicular size/infertility. From 1,264 unrelated patients, the same heterozygous $CEP192$ variant (in family F1) and other variants were associated with male infertility, confirming that $CEP192$ is involved in male infertility. Accordingly, two mice models with equivalent variants were generated. Mutant mice replicated MVA/tetraploidy cytogenetic phenotypes and the susceptibility to male infertility. In Online Mendelian Inheritance in Man (616426), $CEP192$ is a protein coding gene without a clear link to human disease. Thus, the present study should represent the identification of a novel disease-gene $CEP192$ that links to two human diseases, the MVA syndrome with tetraploidy and male infertility.

$CEP192$ encodes a centrosome protein. Centrosomes are organelles that serve as the MTOC for animal cells [ref25-27]. Experiments in vitro by RNA interference indicated that in the M phase, $CEP192$ is important for spindle formation [ref25]; in the interphase, $CEP192$ plays an important role in MT organization (when it depleted, cells became “slim shape”) [ref28].
by focusing on MVA/tetraploidy cellular phenotypes, we identified CEP192 natural variants associated with human disorders. Based on the cells from both human and mice, cells in M phase with CEP192 biallelic variants exhibited disorganized, non-bipolar structures of the spindles; in the interphase, mice fibroblasts with bi-allelic variants exhibited an elongated, bipolar, unipolar, or multipolar cellular shape. Therefore, the present study proved that CEP192 was vital for spindle formation (in mitosis) and normal MT organization (in interphase) from a new perspective.

Notably, the different embryonic development fate was observed between human and mice with CEP192 biallelic variants. Mouse embryos with biallelic Cep192 variants (Cep192<sup>M/M</sup> Cep192<sup>M/-</sup> Cep192<sup>-/-</sup>) were arrested at about E7, whereas human with CEP192 compound heterozygous variants (c.1912C>T/p. H638Y and c.5750A>G/p.N1917S, i.e., the patient A and patient B) were survivable. Such situation may result in subtle differences in one of variants between humans and mice. Cep192<sup>M/M</sup> mice variant (c.5675 A>G/N1892S) was equivalent to human c.5750A>G/p.N1917S variant, while the Cep192<sup>-/-</sup> mice genotype (complete knock out) was different to human c.1912C>T/p. H638Y. In mouse model generation, considering that c.1912C/p. H638 (of human) is not conserved among different species, but majority portion of c.1912T transcripts was undetectable in patient-RNA sequencing (as abnormal spicing), the cep192-knockout mice was generated to mimic the effects of the c.1912C>T/p. H638Y variant. However, unlike the complete knock out in mice, approximately 1% of c.1912T transcripts can be detected in patient cells (Figure 3C). Therefore, approximately 1% of the c.1912T transcripts (that escaping exon 14 skipping) conserve a few CEP192 function that drives cell mitosis. Based on a previous study, U2OS cells with 5% CEP192 function can reserve the capacity to divide, but the cell division and migration were partially blocked [ref 28]. Thus, we proposed here that the complete depletion of CEP192 leads to the failure of cell division, indicating that CEP192 is indispensable in cell mitosis, and cells that conserve a few CEP192 function can divide, but the division speed is slowed down.

Faithful segregation of homologous chromosome and sister chromatid is essential for generating functional spermatozoa [ref 29]. Chromosome segregation errors during meiosis may result in spermatocytes apoptosis, aneuploidy, or tetraploidy and finally cause azoospermia or oligozoospermia and male infertility [ref 30]. CEP192 works as a distinct scaffold to recruit PIK4 to centrosomes [ref 27]. The loss of the CEP192-dependent interaction with PLK4 resulted in
impaired centriole duplication, thus delaying cell proliferation [ref 27]. PLK4 is a known gene for a recessive disorder with partial MVA-related phenotypes [ref 17]. In heterozygous status, PLK4 variants cause male hypogonadism, azoospermia, and germ cell loss in humans and mice [ref18-20]. In the present study, both human and mice with CEP192 heterozygous variants showed susceptible to infertility is probably the mutant CEP192 fails to recruit PLK4.

This has some limitations. In present study, approximately 2030% of male mice with monoallelic Cep192 defect (Cep192<sup>-/-</sup> or Cep192<sup>+-/+M</sup>) were identified to be infertile, from which small testes and histologic changes were observed. However, the remaining fertile Cep192<sup>-/-</sup> or Cep192<sup>+-/+M</sup> male mice exhibited seemingly normal testicular histology. As the embryonic lethality of the Cep192<sup>-/-</sup> or Cep192<sup>MM</sup> mice, the effects in testicular change could not be studied in the homozygous state. Loss of germ cell and reduction in testis size present in a part of the Cep192-heterozygotes mice may be a partial phenotype. The effect of a homozygous Cep192 in the testis could be investigated using a conditional knockout model in our next work.

In conclusion, the present study has identified a novel disease gene CEP192, which links a rare (the MVA syndrome with tetraploidy) and a common disorder (male infertility). These findings expand our knowledge of the relationship between centrosome proteins and human disease and will allow the precise genetic diagnosis of MVA syndrome and male infertility.

**A–B:** Number of litters and total pups from the persistent mating of *Cep192*+/−, *Cep192*+/M, or wild-type males with wild-type females from complete sexual maturity (2 months) to 9 months.

**C:** Testes to body weight ratios of infertile heterozygous mice (*Cep192*+/−, *Cep192*+/M) and wild-type mice at 180 days.

**D:** Representative figure of testes between a *Cep192*+/− mice with infertility and a wild-type mice at 180 days.

**E:** H&E staining of testes (a and b) and epididymides cauda (c) from wild-type mice and infertile heterozygous mice (*Cep192*+/−, *Cep192*+/M) at 180 days old.
**Figure 6**: Alteration in mouse primary embryonic fibroblasts without functional CEP192.

A: Immunofluorescence staining of primary embryonic fibroblasts from wild-type (Cep192\(^{+/+}\)) and knock-out (Cep192\(^{-/-}\)) mice by using antibodies against a centrosome marker protein CEP152 (red), microtubules (green), and DAPI staining of DNA (blue). Top: CEP152 was co-localized with the microtubule organizing center (MTOC) in Cep192\(^{+/+}\) cell; Middle: one CEP152 signal was co-localized with MTOC in Cep192\(^{-/-}\) cell, but the other mutant was not; Bottom: two CEP152 signals were located in cytoplasm that distal to the nuclear (obviously not in MTOC) and a CEP152 signal in MTOC in a uni-polarized cell. Scale bars, 7.5 µm.

B: Immunofluorescence staining of primary embryonic fibroblasts from knock-in (Cep192\(^{M/M}\)) mice by using antibodies against microtubules (green) and DAPI staining of DNA (blue). Left: a bipolar cell; Center: an abnormal multipolar cell; Right: cell in mitosis but without spindle and without microtubule. Scale bars, 7.5 µm.
Figure 7: Mitosis defects and spindle formation abnormalities in cells from a patient with CEP192 biallelic variants.

A–B: Immunofluorescence staining of epithelial cells from a patient patient B and normal control using antibodies against CEP192 (red) and PCNT (green), and DAPI staining of DNA (blue). CEP192 proteins were co-localized with the centrosome in the different stages of mitosis in both cells from normal control and patient B. Scale bars, 7.5 µm.

C–D: Immunofluorescence staining of epithelial cells from patient (patient B) and a normal control using antibodies against CEP192 (red) and α-tubulin (green), and DAPI staining of DNA (blue). C: Normal spindle formation at interphase, metaphase, anaphase, and telophase in epithelial cells were observed in the normal control. D: Two centrosomes were not fully pulled apart per nucleus in epithelial cells from patient. Asterisk indicates the abnormal cells with unevenly distributed nuclei during cell division. Scale bars, 7.5 µm.

E–F: Quantification of different stages in mitosis in epithelial cells from normal control and patient B.
Table 1: Cytogenetic phenotypes of the affected individuals with *CEP192* variants. F1, the index family; MVA, mosaic variegated aneuploidy. NA, not available.

EXPERIMENTAL PROCEDURES

**Human subjects**

Several members in a family were recruited to present study. A total of 1,264 idiopathic infertile men with azoospermia, oligozoospermia, and severe oligo-asthenospermia were recruited. ES data of such cohort of patients with idiopathic infertility have been described previously [ref 31, 32]. The present study was approved by the ethics committee of the Hunan Children’s Hospital (for the index family, approval number: HCHLL201558, Changsha City, Hunan Province, China) or by Institute of Reproductive and Stem Cell Engineering, Central South University (for 1,264 males with infertility, approval number: LL-SC-2017-025 or LL-SC-2019-034, Changsha City, Hunan Province, China). Appropriate written informed consent was obtained from participated subjects or the guardians of the minors.

**G-bands by trypsin using Giemsa (GTG banding)**

The peripheral venous blood of the patients and their family members was collected in a vacutainer sodium heparin vial. Slides were prepared from phytohemagglutinin-stimulated peripheral lymphocyte cultures according to standard cytogenetic methods. In brief, 0.4 mL of whole blood was cultured in lymphocyte medium (5 mL) for 68 h. Then, colchicine (50 µl, 20 µg/mL) was added 2 h before cell harvesting. GTG banding at a 400–500 band level was performed in accordance with the standard laboratory protocol. Two cultures corresponding to two series of slides from each sample were separately prepared and analyzed. At least 40 metaphases were analyzed for each individual. To confirm that the MVA/tetraploidy/PSCS was not occasional, we performed GTG banding for several individuals with interests.

**Histological analysis**

Testes tissues were fixed in Bouin’s solution overnight and then embedded into the paraffin. After the tissue-blocks were sectioned (5 mm thickness), the tissue slides were generated and deparaffinized by xylene. Then the slides were rehydrated by gradient ethanol, sequentially stained with hematoxylin/eosin, and sealed with neutral resin. The images were captured under a microscope (Olympus BX51, Tokyo, Japan).

**ES and variant validation**

Genomic DNA from peripheral blood samples was extracted using a QIAamp DNA blood midi kit (Qiagen, Hilden, Germany) according to the manufacturer’s protocol. ES was performed on four family members as described previously [ref33-34]. Specific PCR primers flanking the suspected variants of CEP192 were used to amplify the region, including Exon14F: 5’- ttgatgtcatttagctgttttacca-3’, Exon14R: 5’-ccatttaacccctaagttacgc-3’, Exon31F: 5’-gcaatcttattttggaaggcgt-3’, and Exon31R: 5’-cgaagccagacaagctgac-3’. The purified PCR products
were sequenced on a genetic analyzer (Applied Biosystems, A3500, CA, USA).

**Total RNA preparation and real-time PCR assay**

Peripheral blood mononuclear cells (PBMCs) were separated from peripheral venous blood, and then cultured in Gibco RPMI 1640 medium (11530586, Thermo Fisher Scientific, USA) with phytohemagglutinin-stimulation for 48 h. Total RNA was extracted from approximately $1 \times 10^6$ PBMCs for each individual by using TRIzol™ (15596026, Thermo Fisher Scientific, USA) according to the manufacturer’s instructions. First-strand cDNA was synthesized using RevertAid first strand cDNA synthesis kit (K1622, Thermo Fisher Scientific, USA). Real-time PCR was performed using SYBR® Green Premix Pro Taq HS qPCR kit (AG171101, Accurate Biotechnology, China) on Roche LightCycler 480 II (Switzerland). The following primers (Forward: 5’-GTGCGCTTGGTGGTGGTAAC-3’; reverse: 5’-GTGCCTGGGACTGTTCATTT-3’, predicted size: 186 bp) were used for CEP192, and primers (5’-ATGGGGAAGGTGAAGGTCG-3’, Reverse 5’-GGGGTCATTGATGGCAACAATA-3’, predicted size: 108 bp) were used for GAPDH (as an internal control). All primers were synthesized by a local biology company (BGI, China).

**Minigene analysis**

Minigene analysis was performed to investigate whether the c.1912C>T variant of CEP192 (exon 14) affect the pre-mRNA splicing in vitro [ref 35]. Amplified-target-fragments generated by standard overlapping PCR using the genomic DNA of the patient (II:2) and digestion were cloned into the plasmids vector. The recombinant vectors (WT and MT) were then transiently transfected into MCF-7 and HEK293T cells by using low-toxicity Lipofectamine following the manufacturer’s instructions (Life Technologies, Carlsbad, CA, United States). Cells were harvested 48 h after transfection, and total RNA was extracted with TRIzol (15596026, Thermo Fisher Scientific, USA). Then, cDNA is synthesized by reverse transcriptase by using a reverse transcription kit (K1622, Thermo Fisher Scientific, USA) according to the manufacturer’s instructions. RT-PCR was performed using specific primers to amplify plasmids containing the exon 14 of CEP192. The primers used in the experiments are shown in Supplementary Table 13. The construction of recombinant plasmids is shown in Supplementary Figure 10.

**Amplicon sequencing**

The human c.1912C>T/p. H638Y variant was located on exon 14 of CEP192. A pair of primers that cover exon 13 and exon 15 was designed (Forward: 5’-GTGCGCTTGGTGGTGGTAAC-3’; reverse: 5’-GTGCCTGGGACTGTTCATTT-3’, predicted size: 186bp). The fragment was amplified using patient’s cDNA with the predicted size of 186 bp. The PCR product was subsequently sequenced on an Illumina platform (Illumina...
Inc., San Diego, CA, USA) to detect the frequency of c.1912T transcript.

**Generation of Cep192 mutant mice**

Two mice models were generated on C57BL/6N by CRISPR/Cas9-mediated genome engineering (Cyagen Biosciences, Suzhou, China), including a knockout (\(\text{Cep192}^{\text{-/-}}\)) and a knock in (\(\text{Cep192}^{\text{+/M}}\)) mice. Exons 6–41 of \(\text{Cep192}\) were deleted from the knock out (\(\text{Cep192}^{\text{-/-}}\)) mouse by using the single-guide RNAs (sgRNA-1: GGC\_GTC\_G\_G\_C\_\_C\_T\_G\_C\_T\_T\_T\_A\_A\_G\_T\_G\_G\_C\_T\_T\_T\_A\_A\_G\_T\_G\_G\_A\_T\_G\_G\), which is equivalent to that observed in patients (c.1912C>T). For generating knock in (\(\text{Cep192}^{\text{+/M}}\)) mouse, a single-guide RNA (sgRNA-3: GT\_G\_G\_T\_C\_T\_T\_A\_A\_G\_C\_A\_C\_A\_T\_C\_G\_G\_G\)) was designed to target c. 5675 A>G/N1892S, which was analogous to the variant p.N1917S in patients. All experiments involving animals were approved by the institutional animal ethics committee of Hunan Children’s Hospital. The strategy and primers sequences used for genotyping the engineered mice are provided in Supplementary Figure 3-4.

**In vitro fertilization in mice**

In vitro fertilization (IVF) was conducted in Cep192 knock-out mice, as described previously [ref 36]. In brief, female mice were superovulated via injection with 10 IU of pregnant mare serum gonadotropin, followed by injection of 10 IU of human chorionic gonadotropin (hCG, Livzon) 48 h later. After 15–16 h, sperm samples collected from mouse cauda epididymides were added into HTF drop (EasyCheck, M1150). Next, cumulus-intact oocytes collected from superovulated female mice were transferred into a sperm-containing fertilization drop. After incubation for 5 h, mouse embryos were washed in another fertilization drop and transferred into the M16 medium (M7292, Sigma-Aldrich) for further culture (37°C, 5% \(\text{CO}_2\)). The fertilization rates were evaluated by recording the number of two-cell embryos and blastocysts at 20 and 96 h later. For genotyping of blastocysts, and whole genome amplification (WGA) was performed using the REPLI-g single cell WGA kit (Cat. No.150343), and the following PCR primers and genotyping parameters are provided in Supplementary Figure 3.

**Fluorescence in situ hybridization in mice cells**

The embryo-cells of the Cep192 mice were analyzed by (FISH and compared with a control sample (wild type mice in the same litter) using a previous reported method [ref 37]. Briefly, the mice embryos were dissected and grinded to single-cell suspension, the suspension was spread on slides, and the cells were fixed, denatured, and hybridized with two specific probes for mouse chromosomes 15 and X (Future Biotech Co., Ltd.). Subsequently, the slides were rinsed, counterstained, and imaged via fluorescence microscopy.

**Immunofluorescence analysis**

Cells were plated in gelatin coated 24-well chamber slides. After 48 h post-plating, the cells were washed with
DPBS and fixed for 20 min with 4% paraformaldehyde. After washing, the cells were permeabilized with 0.1% Triton X-100 for 15 min and blocked for 30 min with 5% bovine serum albumin (BSA). Cells were then incubated with first antibodies in 5% BSA at 4 °C overnight. Cells were washed several times with PBST. After incubating with secondary antibodies for 1 h, the samples were cover slipped with DAPI. Slides were examined and images were captured under the confocal fluorescence microscopy.

For human cells, rabbit anti-human CEP192 (Proteintech, 18832-1-AP, 1:50) and mouse anti-human PCNT (Abcam, ab28144, 1:100) were used to analyze the centrosome formation CEP192 colocalization; rabbit anti-human CEP192 and mouse-anti human α-Tubulin (Cell Signaling Technology, #3873S, 1:100) were used to analyze spindle formation. The stage frequency of spindle formation was analyzed by analyzing at least 100 nuclei per slice via randomly selected field from each slice by two independent researchers who were blinded to the status.

For mouse embryo cells, rabbit anti-mouse CEP152 (GeneTex, 128027, 1:100) was used to analyze the centrosome location of a cell. Mouse-anti mouse α-tubulin (Cell Signaling Technology, #3873S, 1:100) was used to stain microtubules.

**TUNEL assay**

Terminal deoxynucleotidyl transferase dUTP nick-end labelling (TUNEL) assay (DeadEndTM Fluorometric TUNEL System, Promega, Madison, WI, USA) was performed, according to the manufacturer’s instructions, on the cells collected from the Cep192-mutant mice-embryos (both the homozygous or heterozygous genotype) and from wild type mice-embryos (from the same litter).

**Mouse embryo-cells cultured in vitro**

E9 embryos (Cep192/M/M, Cep192/-/- and wild-type) were used to generate mouse embryonic fibroblasts. Briefly, the whole embryo was minced and trypsinized in 0.25% trypsin for 15 min at 37 °C. Cells were released through mechanical trituration and grown in Dulbecco’s modified Eagle medium, 10% fetal calf serum, and 100 μg of penicillin–streptomycin per ml.

**Human epithelial cells cultured in vitro**

Sterile urine was collected from patient B and an age- and gender-matched control. The outgrowth epithelial cells from urine were collected and seeded onto a gelatin-coated 12-well plate in renal epithelial cell growth medium (REGM BulletKit, Lonza). When epithelial cells were 70%–80% confluent, all cells were subcultured at the next passage with a 1:4 split ratio. During passages 1–3, the epithelial cells were used for the following experiment or frozen in liquid nitrogen for future use. The genotype of cell lines was confirmed by PCR amplification and Sanger sequencing using the primer mentioned above.
Statistical analysis

In the genetic association analysis, two control groups were used, namely, the public Chinese control group (Huabiao-5000 human-exome-sequencing-data of general Chinese-Han-population, https://www.biosino.org/wepd) and the EAS_gnomAD control group (CEP192 variants data downloaded from http://www.gnomad-sg.org/).

Logistic regression analysis was used to estimate the association between a variant (that appears twice or more in 1264 infertile males) and infertility. Statistical significance was considered when p < 0.05. Statistical analyses were conducted using IBM SPSS 20.0 (IBM SPSS, Inc., Chicago, IL).
