Abstract

Introduction: Blood biomarkers have proven useful in Alzheimer’s disease (AD), but little is known about their biological variation (BV), which plays a crucial role in the interpretation of individual patient data.

Methods: We measured plasma amyloid-β (Aβ42, Aβ40), phosphorylated tau (p-tau181, p-tau217, p-tau231), glial fibrillary acidic protein (GFAP), and neurofilament light chain (NFL) in fasting plasma samples collected weekly over 10 weeks from 20 participants aged 40-60y from the European Biological Variation Study. We determined within-subject (CVI) and between-subject (CVG) BV, analytical variation (CVa) and reference change values (RCV).

Results: Biomarkers presented considerable variability in CVI and CVG. Aβ42/Aβ40 had the lowest CVI (~3%) and p-tau181 the highest (~16%), while the others ranged from 6-10%. Most RCVs ranged from 20-30% (decrease) and 25-40% (increase).

Interpretation: We provide BV estimates for AD plasma biomarkers, which can potentially refine their clinical and research interpretation. RCVs might be useful for detecting significant changes between serial measurements when monitoring early disease progression or interventions.

Keywords: biological variation, analytical variation, plasma biomarkers, p-tau, amyloid, glial fibrillary acidic protein, neurofilament light, reference change values
Highlights

∙ Plasma Aβ42/Aβ40 presents the lowest between- and within-subject biological variation, but also changes the least in AD patients vs controls.

∙ Plasma p-tau variants significantly vary in their within-subject biological variation, but their substantial fold-changes in AD likely limits the impact of their variability.

∙ Plasma NfL and GFAP demonstrate high between-subject variation, the impact of which will depend on clinical context.

∙ Reference change values can potentially be useful in monitoring early disease progression and the safety/efficacy of interventions on an individual-level.

∙ Serial sampling revealed that unexpectedly high values in healthy individuals can be observed, which urges caution when interpreting AD plasma biomarkers based on a single test result.
Research in Context

Systematic Review:
We reviewed PubMed for articles and conference abstracts that evaluated the biological variation (BV) of novel Alzheimer’s disease (AD) blood biomarkers. Two previous studies had reported BV estimates for serum glial fibrillary acidic protein (GFAP) and neurofilament light chain (NfL). Thus, we aimed to provide the first robust BV estimates for plasma amyloid-β (Aβ) and phosphorylated tau (p-tau) biomarkers, and also for plasma GFAP and NfL in the same population.

Interpretation:
Plasma biomarkers of key pathological features of AD demonstrate heterogeneity in their within- and between-subject variation. Plasma Aβ42/Aβ40 generally shows lower variability but also changes very modestly in AD patients vs controls. While plasma p-tau variants demonstrate higher variability, its clinical impact is likely limited due to large fold-increases in AD. Plasma NfL and GFAP had the largest between-subject variability, which may impact upon their application in certain contexts. Most research on blood biomarkers so far has been done using either single measurements or repeated measurements over longer (e.g., yearly) time frames; the weekly serial sampling in our study revealed that unexpected outlier values may occur, urging caution in clinical and research interpretation.

Future directions:
Future studies should evaluate the potential clinical impact of the application of BV knowledge upon clinical and research interpretation of AD plasma biomarkers, especially in disease monitoring and in the evaluation of safety and efficacy of novel therapeutic interventions.
1. Introduction

Novel technologies to measure brain pathophysiological processes in the blood have revolutionized the Alzheimer’s disease (AD) research landscape.\textsuperscript{1,2} Established and highly accurate methods for tracking such processes face barriers to their large-scale implementation, such as the high costs, radiation exposure and limited availability of positron emission tomography (PET) scans, as well as the relative invasiveness of lumbar punctures, required for measuring AD biomarkers in the cerebrospinal fluid (CSF).\textsuperscript{3} Blood-based AD biomarkers have demonstrated great promise so far, and are particularly promising for scalable implementation due to their minimally invasive and cost-effective nature.\textsuperscript{1,2}

Among blood-based biomarkers so far investigated, plasma phosphorylated tau (p-tau) variants, such as p-tau181, p-tau231 and p-tau217, have demonstrated the greatest potential to identify AD-specific processes, showing high accuracy for identifying neuropathological or biomarker-confirmed AD and predicting cognitive decline.\textsuperscript{4-8} While p-tau231 may be more sensitive to incipient amyloid-β (Aβ) pathology, plasma p-tau217 seems the most well-suited for clinical implementation, presenting the highest fold-increases in cognitively impaired patients with AD-type pathology, and it can dynamically track longitudinal AD clinical progression.\textsuperscript{4,6,7,9-11} Plasma Aβ, in the form of the Aβ42/Aβ40 ratio, has also shown good performance in detecting Aβ pathology, but its modest fold-change (reduced by 8-14% in AD compared with Aβ-negative controls, when in the CSF it is reduced by >50%)\textsuperscript{12,13} makes it more vulnerable to analytical fluctuations normally observed in a day-to-day clinical chemistry routine.\textsuperscript{14-16} Plasma levels of glial fibrillary acidic protein (GFAP), a cytoskeletal protein highly expressed in reactive astrocytes\textsuperscript{17}, have been positively associated with early Aβ pathology.\textsuperscript{18-21} Neurofilament light (NfL), a marker for axonal damage, has gained increasingly clinical significance with robust evidence for its diagnostic and prognostic utility in a wide range of neurodegenerative diseases (AD, frontotemporal dementia, atypical parkinsonian disorders) and in acute neurological conditions, such as stroke and traumatic brain injury.\textsuperscript{22-26} Furthermore, all of these biomarker candidates have been evaluated as potential surrogate endpoints disease-modifying clinical trials in AD, with a recent example being reductions in plasma p-tau217 as early as after 12 weeks of treatment with a promising anti-Aβ monoclonal antibody, donanemab.\textsuperscript{27}
Nevertheless, several research questions must be addressed before the large-scale implementation of blood-based AD biomarkers. While most studies focused on their diagnostic and prognostic properties, little is known about their biological variation (BV) – a foundational concept in clinical chemistry, crucial to ensure the safe implementation of diagnostic markers and to minimize misclassification risks in laboratory medicine. BV refers to the variation observed in clinical laboratory measurements determined by patients’ physiology, and a strict guideline-defined methodology must be followed by BV studies to ensure robust results. Such studies require the serial, tightly controlled collection of samples from healthy individuals with a regular sampling rate, and that analytes should be quantified, at least, in duplicate. The key BV components are the within-subject biological variation (CV\(_i\)), which informs how much the concentration of a biomarker fluctuates around each individual’s homeostatic setpoint, and the between-subject biological variation (CV\(_c\)), which informs on the variability between the homeostatic setpoints between different individuals. These parameters, alongside known assay-dependent analytical variation (CV\(_\lambda\)), can provide highly clinically useful information for biomarker implementation. These include the reference change value (RCV), which enumerates the change needed between consecutive measurements to exceed biological and analytical variation, the analytical performance specifications (APS) that clinical-grade assays should meet, and the index of individuality (II), which evaluates the utility of population based reference intervals. Thus, high-quality BV data is needed in this rapidly developing area of AD diagnostics, in which specific biomarkers and assays are being considered for clinical implementation and therapeutic trial use.

Here, we aimed to determine BV estimates for plasma Aβ42, Aβ40, Aβ42/Aβ40, p-tau181, p-tau217, p-tau231, GFAP and NfL (and associated APS and RCVs) in healthy adults between 40-60 years from the European Biological Variation Study (EuBIVAS), led by the European Federation of Laboratory Medicine (EFLM) Working Group on Biological Variation. The EuBIVAS is a highly powered multicenter study that included weekly blood sampling over 10 weeks from presumably healthy volunteers from five European countries and that has delivered high-quality BV estimates for many measurands, widely used in diverse medical areas.
2. Methods

2.1 Study participants and sample collection

In this study, we quantified biomarkers in plasma-citrate samples from a subset of 20 individuals aged between 40-60 years within the EuBIVAS,\(^{37,38}\) which originally enrolled 91 healthy volunteers (53 females; 38 males; ages 21-69 years), from six European laboratories located in five different countries (Italy, Norway, Spain, Turkey and the Netherlands). We chose to include in the current study those in the older EuBIVAS age range that had sufficient sample material for analyses. Information on the participants’ health status and lifestyle was collected with an enrollment questionnaire, and participants were screened at enrollment with a selection of laboratory tests to further confirm compatibility with inclusion criteria. Fasting blood samples were collected weekly over 10 consecutive weeks for each study participant (April-June 2015), always in the morning. At each center, samples were centrifuged at 3000 g for 10 min at room temperature within 1h of the blood draw, aliquoted and frozen rapidly by immersion in a bowl with methanol and dry ice, and sent to the coordinating center (San Raffaele Hospital in Milan, Italy), where they were stored at -80°C. In November 2021, the samples included in this study were sent to the Clinical Neurochemistry Laboratory (Sahlgrenska University Hospital, Gothenburg, Sweden), where the AD blood biomarkers were measured (April 2022, except p-tau217, analyzed December 2022). Further details regarding the inclusion/exclusion criteria, health status, and sample collection, processing, and storage protocol used in EuBIVAS have been previously reported.\(^{37}\)

The protocol for EuBIVAS received approval from the Institutional Ethical Review Board of San Raffaele Hospital, in compliance with the World Medical Association Declaration of Helsinki, as well as the Ethical Board/Regional Ethics Committee for each participating center.

2.2 Biomarker quantification

Biomarker quantification was conducted using Single molecule array (Simoa) HD-X Analyzers from Quanterix (Billerica, MA/USA) at the Clinical Neurochemistry Laboratory of Sahlgrenska University.
Hospital in Sweden. A commercially available assay (Quanterix Neurology-4 Plex E) was used to simultaneously quantify for Aβ42, Aβ40 (and Aβ42/Aβ40, consequently), NfL, and GFAP. P-tau231 and p-tau181 were analyzed using Simoa assays developed at the University of Gothenburg, which have been validated as described elsewhere. To measure p-tau217, a novel commercially available assay from ALZpath (ALZpathDX, Carlsbad, CA/USA) was used. All samples from the same participant were analyzed in the same analytical run, and each sample was quantified in duplicate. Internal quality controls (iQC) at three different concentrations, for each measurand, were analyzed in duplicate in the beginning and end of each run. Before analysis, blood samples were thawed, vortexed, and centrifuged at 4000 × g for 10 minutes as suggested in recent studies.

2.3 Statistical analysis

Our statistical analyses followed a series of well-established and guideline-defined steps for deriving BV data, as set out by the Biological Variation Data Critical Appraisal Checklist (BIVAC), a standard for the executing and reporting of BV studies. Outlier detection procedures were performed on three levels, including analytical (between replicates), within-subject (among 10 collections for CV\textsubscript{I} calculation), as well as on the between-subject level (for CV\textsubscript{G} calculation). For obtaining CV\textsubscript{I} and CV\textsubscript{A} estimates, we initially performed CV-transformation of the data where each person's data is “normalized” by dividing it by that person's mean value, so as to later perform the ANOVA on these CV-transformed values. After CV-transformation, we performed outlier identification and removal on the analytical levels (between replicates) by assessing the homogeneity of CV\textsubscript{A} with the Bartlett test. In case of heterogeneity for the analytical component, we first excluded the replicate value of the measurement that most deviated from that participant’s mean. If the heterogeneity persisted, we then also excluded the second measurement result of the time-point showing abnormal analytical variation. After ensuring analytical homogeneity, we evaluated the presence of outliers on the within-individual variation level by assessing the homogeneity of the within-individual CV\textsubscript{I} with the Cochran test. Then, we evaluated for each biomarker, whether the results were consistent with steady state (i.e. no trend for increase or decrease during study) by fitting a linear
regression model with the mean blood drawing value (pooled mean of the duplicate concentration measurements of each participant) as the dependent variable, with blood drawing number (from 1-10) as the independent variable. Individuals were considered to be in a steady state if the 95% CI of the blood draw term (i.e., the slope) included 0.52 Finally, the CVI was estimated with CV-ANOVA, the “Røraas method”, a validated and recommended ANOVA method for estimating CVI and CVα.51,53 To calculate the between-subject biological variation (CVG), we first applied the Dixon-Q test to detect outliers in mean biomarker concentrations between subjects, and the Shapiro-Wilk test to verify the normality assumption on mean concentrations. If the latter tests detected a non-normal distribution, concentration data were natural log-transformed, prior to obtaining the CVG by ANOVA.46–50 First, CVI and CVG estimates were calculated for the whole study population, and also secondarily separately for males and females, for all measurands. Confidence intervals (CIs) for BV estimates were calculated as previously described,54 and the lack of overlap of the 95% CI of estimates was used to indicate significant differences between subgroups.

Other relevant metrics were computed based on the above-mentioned BV estimates were calculated as follows. Desirable analytical performance specifications (APS) were calculated for imprecision (CVAPS = 0.5xCVI) and for bias [BiasAPS = 0.25x√(CVI² + CVG²)]. The reference change value (RCV) was calculated at a 95% bidirectional alpha (z=1.65) as RCV = 100*(exp(±zσ/√2σ)–1), where σ=√ln(CVI² + CVI²), with σ²CVI = ln(CVI² + 1) and σ²CVa = ln(CVa² + 1). The index of individuality (II) was calculated as the ratio of CVI and CVG for each biomarker, and indicates whether population-based reference intervals can be useful for evaluating results.33,36 We also calculated the number of samples needed to be collected to estimate an individual’s homeostatic point (NHSP) with a “D” absolute percentage proximity to the individual’s true value with the equation n = (z²/σ²)(CVI² + CVA²)/D², in which z=1.96, corresponding to a 95% alpha. NHSP was calculated based on 5, 10 and 20% deviations from the homeostatic setpoint. Metrics such as RCVs and APS were always derived based on CVI and CVG of all participants. All analyses were performed with R Statistical Software (version 4.2.1; www.r-project.com), and statistical significance was set as alpha=0.05.
3. Results

3.1 Participant characteristics

We included data analyzed from a total of 196 plasma samples, collected weekly over 10 weeks from 20 participants, with a mean number of 9.8 samples per participant. Key demographic information is described in Table 1. The age range of the included participants was 40-60 years, with a mean (SD) age of 46.4 years (6.20) for the whole study population. Half of the participants were female, and key demographic characteristics were generally similar between sexes. The study population came from 5 centers in 4 European countries (Italy [n=7], Netherlands [n=5], Norway [n=5], Spain [n=3]), and all participants were white/caucasian. Participants were healthy, with a mean (SD) body mass index of 23.3 kg/m$^2$ (2.85 kg/m$^2$), did not have hypertension, and the majority (55%) engaged in physical activity for more than 3 hours per week. Only one participant was a smoker (5%), and 11 reported consuming 1-2 units of alcohol per week.

3.2 Homogeneity analyses and outliers

Table 2 displays results of the homogeneity analyses for outlier detection and the final number of results included for each of the biomarkers. All samples were always analyzed in duplicate, except in very few cases with insufficient volume left, resulting in a mean of 1.97 replicate quantification per sample per biomarker. When evaluating the analytical homogeneity with the Bartlett test, no outliers for the replicate measurement were identified for Aβ40, Aβ42/Aβ40, GFAP, and NfL, while a few replicates were excluded for Aβ42, P-tau181, P-tau217, and P-tau231. When assessing the variance homogeneity for within-subject variation, outlier time points were identified for all biomarkers, but no subject had to be fully excluded. For the total study population, the mean percentage of results identified as outliers at the homogeneity analyses was 3.56% (range, 1.0–6.8%), which left a mean of 369 results (range, 332–381) used per biomarker to estimate the CV$_I$.

In Figure 1 the 10-week biological variation, in concentrations, of each plasma biomarker, stratified by sex and ordered by increasing age is displayed. In a separate outlier detection procedure before the CV$_G$
estimation, the Dixon-Q test identified 1 outlier subject for NfL, and 2 outlier subjects for Aβ42/Aβ40 (indicated in Figure 1). No trend was identified for any of the included biomarkers in the overall study population or in male or female subgroups. No biomarker measurement for any analyte was below the lower limit of detection or the lower limit of quantification.

3.3 Analytical performance (CVₐ)

The CVₐ for each biomarker, which indicates the imprecision between duplicate measurements, and associated 95% CIs are graphically displayed in Figure 2A and numerically represented in Table 3. The CVₐ ranged from around 3% for all Aβ biomarkers (Aβ42: 2.8%; Aβ40: 2.6%; Aβ42/Aβ40: 3.0%), to around 6% for GFAP (6.4%) and NfL (6.3%), and to approximately 5.5% for all p-tau biomarkers (p-tau181: 5.6%; p-tau217: 5.7%; p-tau231: 5.6%). Analytical variability of internal quality controls presented similar CVs to those estimated with CV-ANOVA, and no systematic trends in concentration change between-runs were observed by visual inspection.

3.4 Within-subject biological variation (CVᵢ)

Figure 2B graphically represents the CVᵢ values and their associated 95% CIs, i.e., how much biomarker concentrations fluctuate around each individual’s homeostatic setpoint. Plasma Aβ42 and Aβ40 demonstrated low and very similar CVᵢ’s (Aβ42: 6.5%, 95% CI 5.8-7.3; Aβ40: 6.4%, 95% CI 5.7-7.1), and the plasma Aβ42/Aβ40 ratio demonstrated the lowest CVᵢ among all evaluated biomarkers (3.3%, 95% CI 2.9-3.9). Among plasma p-tau variants, p-tau231 demonstrated the lowest CVᵢ (6.3%, 95% CI 5.5-7.4), followed by p-tau217 (10.3%, 95% CI 9.2-11.7), and by p-tau181 with a considerably higher CVᵢ (16.7%, 95%CI 15.0-18.6). Plasma GFAP also demonstrated a relatively low CVᵢ (8.0%, 95% CI 7.0-9.2), comparable to that observed for NfL (7.4%, 95%CI 6.4-8.5). In Table 3, the CVᵢ’s are also shown separately for males and females, an important and needed subgroup analyses in BV studies. Except for p-tau181, no differences in CVᵢ were observed for the evaluated biomarkers, with overlapping 95% CIs for male and
female CV's. For plasma p-tau181, females (19.7%, 95% CI 16.9-22.9) demonstrated a higher CV than males (13.3%, 95% CI 11.4-15.5).

3.5 Between-subject biological variation (CV_G)

Figure 2C graphically represents the CV_G values and their associated 95% CIs, i.e., how much biomarker levels vary between healthy individuals. Among Aβ biomarkers, plasma Aβ42/Aβ40 demonstrated the lowest CV_G (6.6%, 95% CI 4.6-9.3), with higher and similar estimates for Aβ42 (15.3%, 95% CI 11.1-21.1) and Aβ40 (12.5%, 95% CI 9.0-17.4). For the other biomarkers, CV_G's were generally higher than those for Aβ biomarkers. GFAP demonstrated the highest CV_G among all biomarkers (30.1%, 95% CI 21.8-41.6), and slightly higher than that of NfL (21.2%, 95% CI 15.1-29.8). Among p-tau biomarkers, p-tau231 (17.2%, 95% CI 17.2-19.7) demonstrated the lowest CV_G, followed by p-tau217 (21.1%, 95%CI 15.1-29.3) and p-tau181 (25.7%, 18.3-36.1%). Table 3 indicates the CV_G's separately for males and females. No differences in CV_G estimates were found for the evaluated biomarkers, with overlapping 95% CIs between males and females for all measurands. Table 3 also shows the mean concentrations and their 95% CIs for males and females separately, with slightly higher concentrations in females observed for plasma GFAP and NfL, and slightly higher concentrations in males for plasma p-tau181 and p-tau231.

3.6 Analytical performance specifications and other metrics

Table 4 shows analytical performance specifications (APS) based on the desirable criteria (intermediate stringency), for imprecision, bias. In terms of desirable assay imprecision, the highest demand was for plasma Aβ42/Aβ40 (CV_{APS}<1.7%), with the lowest demands for plasma p-tau217 (CV_{APS}<5.2%) and p-tau181 (CV_{APS}<8.4%). Table 4 shows the estimated reference change values (RCV), as well as the number of samples needed to estimate the homeostatic point. Plasma Aβ42/Aβ40 demonstrated the lowest RCVs needed for a significant decrease (11%) and for na increase (13%). Similar RCVs for both decrease
(-20 to -28%) and increase (26 to 38%) were observed for GFAP, NfL, p-tau217 and p-tau231, with the highest RCVs for p-tau181 (decrease: -38.3%; increase: 62.2%).

4. Discussion

In this study, we report BV estimates for novel AD plasma biomarkers generated based on a high number of weekly samples per individual, with a comprehensive biomarker panel measured within the same participants. These are the first reported BV estimates for blood Aβ42, Aβ40, Aβ42/Aβ40, and p-tau, but also for plasma NfL and GFAP, which had their BV previously evaluated in serum.55-57 We found that within- and between-subject biological variation can be considerably different for each AD biomarker class, which may inform and impact biomarker application given each clinical or research context.

In addition to improving clinical and research interpretation of these biomarkers, reliable BV data enables the determination of the APS needed for each biomarker. In short, the assay imprecision (i.e. CVA) should be considerably lower than the biomarker’s CVI, with the desirable imprecision analytical performance being that CVA≤CVI/2.58 Here, CVA’s were slightly higher than desired for most biomarkers. Plasma Aβ42 and Aβ40 (but not Aβ42/Aβ40) and plasma p-tau181 were within the desirable performance, with plasma p-tau217 showing a very close to desirable analytical performance (CVA: 5.7%; CVAPS: ≤5.2%). Nevertheless, it is important to emphasize that BV estimates are not standalone criteria to determine APS for assays, but rather a complementary tool to refine the determination of analytical goals given each analyte’s clinical application context. For instance, the higher-than-desirable observed CVA’s are likely not a cause of concern in light of the main clinical applications of NfL and p-tau variants, whereas it might affect more Aβ42/Aβ40, as discussed below.

Plasma p-tau is an AD-specific biomarker envisioned to be implemented as a screening tool to classify patients seeking medical advise for cognitive symptoms into high-, intermediate- and low-risk of having AD pathology.59,60 The emergence of plasma p-tau assays has sparkled a debate on potential differences between p-tau phospho-sites.2 In our study, CVA was remarkably similar for all three plasma p-tau variants, but they demonstrated considerably different CVI’s. Interestingly, p-tau231 demonstrated the
lowest CV\textsubscript{1} (6.3\%, 95\%CI 5.5-7.4\%), followed by p-tau217 (10.3\%, 95\%CI 9.2-11.7\%) and p-tau181 (16.7\%, 95\%CI 12.5-23.6\%). These may suggest differences in release, clearance or transportation of plasma p-tau species. Recent head-to-head comparisons of plasma p-tau variants showed the most promising candidates were increased between 100-360\% in the presence of AD pathology.\textsuperscript{9,10} Taking the magnitude of these increases into account, it seems reasonable to state that the currently used p-tau assays demonstrate a satisfactory analytical performance for clinical applications, having their diagnostic ability less vulnerable to biological and analytical variation.

Plasma NfL has been successfully introduced in clinical routine in some laboratories, being useful both in a wide range of neurodegenerative diseases and in acute neurological conditions.\textsuperscript{22,24,26,61} Plasma NfL showed a relatively low CV\textsubscript{1} (7.4\%, 95\%CI 6.4-8.5\%), and a higher CV\textsubscript{G} (21.2\%, 95\%CI 15.1-29.8\%). This is in accordance with the ~10\% CV\textsubscript{1} and CV\textsubscript{G}’s reported in a previous BV study evaluating serum NfL in a Turkish cohort, with a different analytical platform, but also with 10-week weekly collection.\textsuperscript{57} Our RCVs for NfL (increase: +30.7; decrease: -23.4\%) also closely agreed with those in that study (increase: +32.7; decrease: -24.7\%). A different study in a Danish cohort reported a substantially lower CV\textsubscript{1} for serum NfL (Simoa) with non-overlapping CIs (CV\textsubscript{1}=3\%, 95\%CI 1.2-5.0\%), and lower RCVs (increase: +24.3; decrease: -19.5\%).\textsuperscript{56} The lower NfL CV\textsubscript{1} in this cohort could be attributed to the shorter sampling period of three consecutive days, which may lead to lower BV estimates, compared with the 10-week weekly collection in both ours and the Turkish study.\textsuperscript{62} The relatively high CV\textsubscript{G} seen for plasma NfL reflects higher inter-individual variability, posing a challenge to its clinical interpretation in conditions with modest NfL fold-changes such as AD, where the diagnostic utility of NfL is limited. However, in certain clinical scenarios, this between-subject variation is likely of limited importance, including differentiating primary psychiatric disorders from frontotemporal dementia,\textsuperscript{63} or in prognostic evaluation of acute conditions such as cardiac arrest, stroke and traumatic brain injury.\textsuperscript{24,26,64} In these cases, the magnitude of NfL increases is much larger compared to relatively higher CV\textsubscript{G}’s.

We also provide BV estimates for plasma GFAP. While it is not yet clear what GFAP in the blood reflects, with differences against CSF GFAP,\textsuperscript{65} it has been associated with Aβ pathology and demonstrated
promising diagnostic performance\textsuperscript{18,20}, but with some studies reporting increased levels in Aβ-negative neurodegenerative disorders, e.g. frontotemporal lobar degeneration.\textsuperscript{66} We observed a relatively low CV\textsubscript{1} for plasma GFAP (8.0\%, 95\%CI 7.0-9.2), and the highest CV\textsubscript{G} among all evaluated biomarkers (30.1\%, 95\%CI 21.8-41.6\%). The estimated CV\textsubscript{1} was similar to a previously reported CV\textsubscript{1} for serum GFAP (9.7\%, 95\%CI 7.6-11.8), and while their CV\textsubscript{G} was slightly higher (39.5\%, 95\%CI 31.7-47.3), it was still in a similar higher tier, with RCVs also agreeing between studies. Plasma GFAP presents a high CV\textsubscript{G}, which, alongside its poorly understood clinical meaning, indicates potential difficulties for its individual-level interpretation.

We report here the first BV estimates for plasma Aβ. Plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} is a widely investigated biomarker associated with Aβ pathology currently in clinical use in to support AD diagnosis.\textsuperscript{12,67,68} However, in Aβ-positive vs Aβ-negative individuals, plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} is only decreased by 8-14\%.\textsuperscript{13} This clinical context places, per se, a robustness issue for this biomarker, since the modest disease-related fold-changes are in a similar magnitude to that of common analytical variation results seen in clinical chemistry.\textsuperscript{2,14-16} Our novel BV findings further support that the implementation of plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} will likely face difficulties if introduced in clinical practice. Plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} demonstrated a considerably low CV\textsubscript{1} (3.3\%, 95\%CI 2.9-3.9), and a relatively low CV\textsubscript{G} (6.6\%, 95\%CI 4.6-9.3). The low CV\textsubscript{1} introduces a very high demand on analytical performance, since, desirably, the CV\textsubscript{A} should be less than half of the CV\textsubscript{1} (CV\textsubscript{APS}=1.7\%; Table 4), and optimally, less or equal to a quarter of CV\textsubscript{1} (CV\textsubscript{1}/4=0.7\%). This occurs in a different clinical context to that of plasma p-tau, where larger disease-related increases make the ~5.5\% CV\textsubscript{A}’s acceptable. Additionally, while there are several different plasma Aβ assays currently in use, they present similarity in their small disease-changes.\textsuperscript{13} Considering previous BV studies showing different assay versions for the same analyte present indistinguishable CV\textsubscript{1}’s, it is expected that the CV\textsubscript{1} for plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} would be similar across assays.\textsuperscript{47,52} Further, the desirable bias is also considerably low for plasma Aβ\textsubscript{42}/Aβ\textsubscript{40} (B\textsubscript{APS}=3.7\%; Table 4), and it is unlikely that batch-to-batch variations could be kept low enough to meet it.

Here, we report RCVs for AD plasma biomarkers, a potentially clinically valuable tool not yet explored in the AD field. By enumerating the change that can be explained by biological and analytical
variation, when monitoring an individual with consecutive tests over time, more informed clinical decisions can be made. This becomes especially relevant with novel anti-Aβ immunotherapies such as lecanemab and donanemab.²⁷,⁶⁹ These drugs have been shown to substantially reduce plasma p-tau217, in a group-level, as early as at 12 weeks of treatment (with our RCVs derived in a similar time frame), during the initial phase of Aβ-plaque reduction.²⁷ RCVs could be potentially used to identify whether a reduction in plasma p-tau217 after treatment initiation could indeed be related to a positive treatment response, provided trial data support an individual-level association between p-tau reduction and benefit. On the other hand, this class of drugs can cause amyloid-related imaging abnormalities (ARIA) of the hemorrhage or edema type, which can be very harmful.⁷⁰ If NfL proves capable of tracking such changes (currently unknown from current trials), RCVs could also be potentially useful to monitor their emergence. However, it is important to take into account that our RCVs were obtained using the presumably healthy cognitively unimpaired sample and assays herein described, and, for this reason, cannot be considered as universal values, and each laboratory has to determine their own RCVs based on their CVₐ estimates.

Our study provides important novel data for interpreting of AD blood biomarkers. Most published studies have collected samples either cross-sectionally or over longer periods of time (e.g. 6 months, yearly), and little is known about their shorter-term variability, with a BV study like ours providing a unique opportunity to evaluate shorter-term fluctuations. Figure 3 shows plasma p-tau181 and p-tau217 over the study period male subjects with similar ages. Subject “A” shows minimal fluctuation around the homeostatic point, while subject “B” experiences two spikes in plasma p-tau. These fluctuations were not analytical outliers, and since a chronic disease like AD is unlikely to manifest an oscillatory progression from week-to-week in middle-aged adults, there might be yet uncharacterized factors influencing biomarker readings. Clinical decisions made on a single sample collected on a p-tau “spike” day could erroneously classify patients as “abnormal”, as exemplified by two previously described cut-offs.⁴³,⁷¹ Such high-value outliers are not uncommon in Aβ-negative groups when examining data points from recent cross-sectional studies,⁴–⁶ and we recommend caution for researchers and clinicians when interpreting AD blood biomarker results from a single sample.
Additionally, knowledge of CVI enables calculating the number of samples needed to estimate the individual’s homeostatic point (HSP) within a certain proximity of the true value. To estimate the true HSPs of all analytes with a deviation of ±20% (α<0.05), a reasonable margin for most analytes here (given clinical contexts discussed above), one sample suffices for all biomarkers but p-tau181 (NHSP=3). Reducing this deviation to 5%, likely needed for plasma Aβ42/Aβ40 (but not for other biomarkers), three samples would be required (Table 4). The II evaluates the utility of reference intervals (RIs). For analytes with pronounced individuality and a relatively low CVI compared to CVGI (II<0.6), RCVs are more useful than RIs for accurate interpretation of sequential results, with each individual serving as the optimal reference point for assessing serial. However, RIs remain suitable for analytes with high II (particularly when II>1.4).33,36 Here, all II values were below 0.6, except for p-tau181 and Aβ42/Aβ40, which had slightly higher values, indicating marked individuality for these analytes and suggesting the potential for personalized reference intervals.33,36,72

This study has limitations. Although well-powered in individual-level serial sampling, the number of participants was relatively small, possibly affecting CVGI more than CVI estimates. We found some concentration differences between males and females, and an unexpected sex difference in CVI for p-tau181, warranting further studies. The relatively younger population studied here may not capture biomarker fluctuations related to factors such as co-morbidities and medication use.73 Lack of confirmatory CSF or PET biomarkers prevented us from evaluating the effects of AD pathology over BV estimates. Further evaluation on more diverse populations is also needed. Our study also has a number of strengths, involving quantifying a comprehensive panel of AD biomarkers in a dataset following all EFLM recommendations for BV studies,30,31 that has generated reliable BV data for many other analytes.37,38 In summary, our study provides novel information on the BV of novel AD plasma biomarkers, with important considerations for research, trials and clinical practice.
Figure 1. Participant-level plasma biomarker concentrations over 10 weeks.

The figure displays median (dots) and range (errorbars) of biomarker concentrations over 10 weeks. Females are represented in dark green, and males in orange, and participants are shown with increasing age (subject 1 is the youngest female participant, and subject 20 the oldest male). Triangles represent the concentration outliers detected with the Dixon-Q test before the CVG calculation. CVG: between-subject biological variation; Aβ: amyloid-β; GFAP: glial fibrillary acidic protein; NfL: neurofilament light; P-tau: phosphorylated tau.
Figure 2. Biological variation estimates in the whole study population.

The forest plot graphically summarises the biological variation estimates obtained in this study. (A) The left panel indicates analytical variation ($CV_A$); (B) The middle panel displays estimates for within-individual biological variation; (C) The right panel indicates between-individual biological variation. $CV_I$: within-subject biological variation; $CV_G$: between-subject biological variation; $CV_A$: analytical variation; CI: confidence interval; $A\beta$: amyloid-β; GFAP: glial fibrillary acidic protein; NfL: neurofilament light; P-tau: phosphorylated tau.
Figure 3. Example of 10-week variability in plasma p-tau181 and p-tau217 in two male study participants in their 40s.

The figure shows the variability in plasma p-tau181 and p-tau217 levels over 10 weeks in two study male healthy study participants in their 40s. Dots correspond to the mean concentration of the two duplicate measurements, and all of these subjects’ measurements demonstrated acceptable agreement between replicates, indicating that any deviation observed does not come from analytical imprecision. Dashed lines represent previously published cut-offs for plasma p-tau181 and p-tau217 as illustrative examples of the potential impacts of these fluctuations over decision making. Of note, the outlier data points were excluded from CVI calculations in the homogeneity analyses since they do not reflect the expected homeostatic fluctuation. It is likely that these outlier data points instead correspond to a yet unknown factor that affects biomarker readings. CVI: within-individual biological variation; P-tau: phosphorylated tau.

The table displays each biomarker's desirable analytical performance specifications (APS) for replicate precision and bias. Also, the table displays the reference change values (RCV), which indicate the percentage change needed between two consecutive measurements so that such an increase or decrease significantly overcomes analytical and biological variation. The index of individuality and number of samples needed to estimate the homeostatic point with a given proximity are also shown. CV_{APS}: imprecision analytical performance specification; B_{APS}: bias analytical performance specification; Aβ: amyloid-β; GFAP: glial fibrillary acidic protein; NfL: neurofilament light; P-tau: phosphorylated tau.
