Abstract

Objectives: Diabetic retinopathy (DR) is the leading cause of visual loss in working-age adults worldwide. Cheese is a widely consumed dairy product, and cheese intake has various health benefiting effects. This study aimed to use Mendelian randomization (MR) to investigate the impact of cheese consumption on DR.

Methods: The genome-wide association study (GWAS) summary statistic generated from 451486 European descent was introduced to identify the valid instrumental variables (IVs) for cheese intake. As the outcomes, the GWAS data of three outcome traits (DR, proliferative diabetic retinopathy or PDR, diabetic maculopathy or DMP) were obtained from the FinnGen research project. Multivariable MR (MVMR) analysis was also conducted to determine whether the causal associations were affected by the common risk factors of DR, such as Body Mass Index, systolic blood pressure (SBP), triglycerides (TG), HDL cholesterol and hemoglobin A1c (HbA1c) levels.

Results: The cheese consumption (per 1-SD increase) was found to be associated with a decreased risk of DR (OR=0.701, \(P=0.011\)), PDR (OR=0.671, \(P=0.020\)), and DMP (OR=0.357, \(P=0.001\)). The MVMR analyses demonstrated that the TG level did not affect the causal associations with the decreased risks of DR and PDR. The study on DMP proved that the causal relations were independent from the effect of SBP, TG, and HbA1c levels.

Conclusions: Genetic evidence suggested that cheese consumption was causally associated with the decreased risk of DR. Given widespread cheese consumption, this could have significant implications for global health burdens from DR.

Keywords: Mendelian Randomization; diabetic retinopathy; cheese consumption; causality
1 Introduction

Diabetic retinopathy (DR), the leading cause of visual loss in working-age adults globally, is the most common vascular complication in diabetes mellitus. Proliferative diabetic retinopathy (PDR) and diabetic maculopathy (DMP) are the primarily vision-threatening stages of DR and lead to severe visual impairment, substantially diminishing vision-related quality of life. As the prevalence of diabetes grows yearly, the number of people with DR and the associated healthcare burden are expected to increase dramatically. Although DR can be treated by retinal laser photocoagulation, intravitreal injections, and vitrectomy; the efficacy of these strategies remains insufficient. Therefore, to prevent the onset of DR as well as to delay the progression from early DR to vision-threatening DR are meaningful for alleviating the burden of DR-related blindness. Identifying causal and modifiable risk factors for DR is crucial for providing preventive strategies.

Dietary factors are the key modifiable risk factors that play essential roles in the preventing and managing diabetes. However, compared with diabetes, little is known about the role of diet in the onset and development of DR. Cheese is a staple dairy product that has been reported to be associated with a lower risk of diabetes. Recently, a large observational study on diabetic patients found that higher consumption of cheese may reduce the risk of DR progression. Nevertheless, due to the potential confounding and reverse causation from observational studies, the causal relationship between cheese consumption and DR could not be concluded.

Mendelian randomization (MR) analysis is a powerful statistical method that exploits the random assortment of genetic variants during meiosis to assess the potential causal effect. As an alternative to randomized clinical trials, MR analysis offers an opportunity to investigate the causal effect efficiently. It has become widely used to assess the causal associations of risk factors in diabetes. To the best of our knowledge, so far no MR study has been conducted to investigate the causal role of cheese intake on DR.

2 Materials and methods

2.1 The genetic instrumental variables (IVs) for the consumption of cheese

In order to select the valid IVs for the consumption of cheese, the relevant genome-wide association studies (GWAS) summary dataset of the UK Biobank was acquired and analyzed via the IEU Open GWAS Project (https://gwas.mrcieu.ac.uk/datasets/, GWAS ID: ukb-b-1489). The basic features of the dataset were described in Table 1 and Figure 1.

Fig 1. The workflow describing the MR analysis on the causal association between cheese consumption and DR risks.
According to the MR methodology, three key assumptions are: 1) the included IVs are robustly associated with the exposure trait; 2) they are associated with the outcome only through the exposure; 3) they are independent from the confounders. (See Figure 1.) In order to identify the independent SNPs, we selected the SNPs with $P$ values less than $5 \times 10^{-8}$ for the linkage disequilibrium clumping ($r^2 < 0.001$ within 10000Kb, and using the 1000 Genomes Project Phase 3 (EUR) as the reference panel). When duplicated SNPs were detected, the one with the lowest $P$ value was retained. When the SNPs were unavailable in the outcome’s dataset, the proxy SNPs ($r^2 > 0.8$) were utilized for further analyses. Finally, 64 IVs for cheese consumption were identified to be valid IVs. (See Supplementary Table S1.) We calculated the F statistics to assess the association strength between each SNP and its corresponding trait. The results indicated sufficient statistical power for all SNPs as their F statistics (see Supplementary Table S1) were more significant than 10. The analyzing procedures were performed with the R (version 4.1.3) packages iegwgasr (version 0.1.5) and TwoSampleMR (version 0.5.6).15

2.2 The basic information of three outcome datasets

The GWAS datasets for diabetic retinopathy (DR), proliferative diabetic retinopathy (PDR) and diabetic maculopathy (DMP) were from the Finnish biobank project FinnGen (https://www.finngen.fi/fi/). Their GWAS data was accessed via the platform of the IEU OpenGWAS project (https://gwas.mrcieu.ac.uk/datasets, GWAS ID: “finn-b-DM_RETINOPATHY”, “finn-b-DM_RETINA_PROLIF”, “finn-b-DM_MACULOPATHY”).15, 16 The characteristics of the datasets were shown in Table 1 and Figure 1.

2.3 Univariable and multivariable MR analysis

In the univariable MR (UVMR) analysis, the IVW approach was chosen as the major method, and other analytical tools such as the MR Egger, weighted median, weighted mode, simple mode, and MR-PRESSO were conducted to evaluate the robustness of the results. Moreover, the multivariable MR (MVMR) studies were introduced to explore the potential mechanism through which cheese consumption may influence the DR risk. The common risk factors for DR such as Body Mass Index (BMI), systolic blood pressure (SBP), triglyceride (TG), high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and hemoglobin A1c (HbA1c) levels were introduced into the MVMR analyses. The GWAS summary statistics of the common risk factors were acquired from the platform of the IEU OpenGWAS project (https://gwas.mrcieu.ac.uk/datasets, GWAS ID: “ukb-b-19953”, “ieu-b-38”, “ieu-b-111”, “ieu-b-109”, “ieu-b-110” and “ieu-b-103”, respectively).

2.4 Statistical analysis

Briefly, the IVW method was the major MR analytical tool, and complemented by other approaches such as the MR-Egger, simple mode, weighted median, weighted mode, and MR-PRESSO. The MVMR analysis was conducted to explore the potential mechanism through which the cheese intake may function. All analyses were conducted with R packages MR-PRESSO (version 1.0), iegwgasr (version 0.1.5), and TwoSampleMR (version 0.5.6).15,16,18 A $P$ value less than 0.05 was considered as statistically significant.
3 Results

3.1 The basic features of the included datasets for exposure and outcomes

Three GWAS datasets for the cheese consumption contained 9851867 SNPs’ data covering more than 42000 European participants. (See Table 1. and Figure 1.) As described in the method’s part, 64 IVs were regarded as valid IVs for cheese consumption. The data originated from the studies of the UK Biobank. Three DR-associated datasets from the FinnGen project were selected as the outcome cohorts for further analyses. The sample sizes for DR, PDR, and DMP were 216666 (14584 cases and 202082 controls), 212889 (8681 cases and 204208 controls), and 213377 (1811 cases and 211566 controls), respectively.

3.2 The UVMR analysis from cheese consumption to the risks of three diabetic retinopathies

The results of IVW analyses suggested that a 1-SD increase in cheese consumption was causally associated with a 29.9% decrease in the overall risk of DR (Odds ratio or OR=0.701, $P=0.011$), a 32.9% decrease in the PDR risk (OR=0.671, $P=0.020$) and a 64.3% decrease in the DMP risk (OR=0.357, $P=0.001$). Consistently, the sensitivity studies using MR Egger, Simple mode, Weighted median, Weighted mode, and MR-PRESSO also indicated cheese consumption to be a protective role for DR, PDR, and DMP, though some of them were not statistically significant. (See Table 2. and Figure 2.)

While the $P$ for Cochran’s $Q$ in the IVW analysis on DR was less than 0.05, no heterogeneities were identified to exist in the studies on PDR ($P$ for Cochran’s $Q=0.078$) and DMP ($P$ for Cochran’s $Q=0.588$). (See Table 2. And Figure 2.) No obvious directional pleiotropies were detected in three exposure-outcome pairs since their Egger intercept terms were all centered at the origin (0.006 for DR, 0.001 for PDR, and -0.003 for DMP). Though the MR-PRESSO global studies also suggested no influence for the pleiotropy was observed in the analyses on PDR ($P$-global=0.052) and DMP ($P$-global=0.419), the investigation on DR implied a potential pleiotropy ($P$-global=0.038). The Leave-one-out tests demonstrated that no single SNP could greatly influence the overall estimates. (See
Figure 2.)

3.3 The MVMR analysis from the cheese consumption to the risk of three diabetic retinopathies

As the UVMR suggested the potential causal associations between the consumption of cheese and the risk of three diabetic retinopathies, the MVMR was introduced to investigate the potential mechanisms through which the exposure may influence the outcomes. We found that the TG level did not affect the causal associations with the risks of DR and PDR. (See Figure 3.) The study on DMP proved that the causal relationship was independent from the effect of SBP, TG, and HbA1c levels. (See Figure 3.)
Fig 3. MVMR analyses of causal associations between cheese consumption and DR (A), PDR (B) and DMP (C) adjusted for common risk factors.

4 Discussion

In this two-sample MR study, we explored the causal effects of cheese consumption on diabetic retinopathies by leveraging large-scale GWAS data. This is the first study to show that consuming more habitual cheese was associated with a lower risk of developing diabetic retinopathies, providing a potential new treatment option for DR.

Cheese is one of the most popular dairy products in the world and contains lots of nutrients. In recent years, numerous studies have been carried out to investigate the association between cheese consumption and diabetes risk. Their results revealed that eating cheese is inversely associated with diabetes.19-22 For instance, a large prospective case-cohort study across 8 European countries found a modest inverse association of cheese intake with diabetes.20 In a systemic review and meta-analysis on cohort studies, Aune and colleagues also identified the inverse association between cheese intake and the risk of type 2 diabetes.21 Interestingly, Von Post-Skagegard et al. reported that the protein in cheese has much stronger and quicker-acting glucoregulatory effects than fish protein and plant protein.22 Though previous works have implied the negative association between cheese consumption and diabetes risk; there has been little research exploring the relationship between eating cheese and DR risk. In this MR study, we confirmed that having cheese may be a protective factor for DR. This is in agreement with the results of prior studies on diabetes.

Cheese includes abundant calcium, vitamin D, whey protein, and magnesium. Multiple studies have demonstrated that all the substances as mentioned above are associated with reduced diabetes risk.23-27 This may partially explain the negative correlation between eating cheese and diabetes risk.
Despite the numerous studies on diabetes, to the best of our knowledge, only one published investigation has assessed the association between cheese intake and DR risk by observing the 10-year incidence of DR in diabetic patients in Australia. The study showed that cheese consumption could diminish the risk of DR in diabetic patients. This conclusion stands in line with our current work.

Higher BMI, SBP, HbA1c, LDL, and HDL cholesterol levels were acknowledged as risk factors for DR. Concurrently, these risk factors for DR are influenced by cheese intake: First, in systemic parameters, cheese intake was shown to reduce BMI in a randomized controlled trial. And a recent MR report demonstrated that cheese consumption was causally associated with a lower BMI. Furthermore, the inverse correlation between SBP and cheese intake has also been reported. Secondly, among circulating metabolites, HbA1c has been confirmed by a large RCT meta-analysis to be negatively associated with dairy product intake like cheese. Moreover, multiple RCTs showed that cheese intake could decrease the levels of LDL cholesterol concentration, and increase the HDL-cholesterol concentration levels significantly. In concordance with those of previous studies, our MVMR results indicated that cheese consumption might function to protect DR by affecting these risk factors (see Figure 4). On the other hand, cheese consumption has been proven to be able to alleviate the oxidative stress and inflammatory response, which are the significant factors in the initiation and progression of DR. This may also be one of the underlying mechanisms that cheese consumption suppresses DR (see Figure 4).

![Fig 4. Diagram showing the possible mechanism by which cheese consumption reduces the risk of DR.](image)

Though our work confirmed the causality between cheese consumption and DR risk through the MR framework, it is still limited by the following aspects. First, in the current work, cheese was investigated as a general subject instead of different cheese subtypes. The study with more accurate cheese subclassifications will offer a more precise and robust conclusion as different cheese subtypes vary in the health-associated nutrient components. Second, all the GWAS data analyzed originated from individuals of European descent which may impair the generalizability of the conclusion.

In general, our study firstly reported the inverse association between eating cheese and DR risk from a MR perspective. This finding implies that daily cheese intake may be regarded as a modifiable approach to decrease the DR risk.
