Abstract

**Background:** The Fontan operation is a palliative technique for patients born with single ventricle heart disease. The superior vena cava (SVC), inferior vena cava (IVC), and hepatic veins are connected to the pulmonary arteries in a total cavopulmonary connection by an extracardiac (EC) conduit or a lateral tunnel (LT) connection. A balanced hepatic flow distribution (HFD) to both lungs is essential to prevent pulmonary arteriovenous malformations and cyanosis. HFD is highly dependent on the local hemodynamics. **Objective:** The effect of age-related changes in caval inflows on HFD was evaluated using cardiac MRI (CMR) data and patient-specific computational fluid dynamics (CFD) modeling. **Methods:** SVC and IVC flow from 414 Fontan patients were collected to establish a relationship between SVC:IVC flow ratio and age. CFD modeling was performed in 60 (30 EC and 30 LT) patient models to quantify the HFD that corresponded to patient ages of 3, 8, and 15 years, respectively. **Results:** SVC:IVC flow ratio inverted at ~8 years of age, indicating a clear shift to lower body flow predominance. Our data showed that variation of HFD in response to age-related changes in caval inflows (SVC:IVC = 2, 1, and 0.5 corresponded to ages 3, 8, and 15+ respectively) was not significant for EC but statistically significant for LT cohorts. For all three caval inflow ratios, a positive correlation existed between the IVC flow distribution to both the lungs and the HFD. However, as the SVC:IVC ratio changed from 2→0.5 (age 3→15+), the correlation's strength decreased from 0.87→0.64, due to potential flow perturbation as IVC flow momentum increased. **Conclusion:** Our analysis provided quantitative insights into the impact of the changing caval inflows on Fontan's long-term HFD, highlighting the importance of including SVC:IVC variations over time to understand Fontan's long-term hemodynamics. These findings broaden our understanding of Fontan hemodynamics and patient outcomes.
Keywords: Fontan, hemodynamics, cardiac MRI, computational fluid dynamics, hepatic flow distribution

Clinical Perspective

With improvement in standard of care and management of single ventricle patients with Fontan physiology, the population of adults with Fontan circulation is increasing. Consequently, there is a clinical need to comprehend the impact of patient growth on Fontan hemodynamics. Using CMR data, we were able to quantify the relationship between changing caval inflows and somatic growth. We then used patient-specific computational flow modeling to quantify how this relationship affected the distribution of long-term hepatic flow in extracardiac and lateral tunnel Fontan types. Our findings demonstrated the significance of including SVC:IVC changes over time in CFD modeling to learn more about the long-term hemodynamics of Fontan. Fontan surgical approaches are increasingly planned and optimized using computational flow modeling. For a patient undergoing a Fontan procedure, the workflow presented in this study that takes into account the variations in Caval inflows over time can aid in predicting the long-term hemodynamics in a planned Fontan pathway.
Introduction

A successful Fontan procedure offers complete redirection of systemic venous return, improved arterial saturations, and decreased chronic ventricular volume overload, thereby improving longevity for many patients with single ventricle heart disease (SVHD)\(^1\). The Fontan circulation is the result of a total cavopulmonary connection between the superior vena cava (SVC), inferior vena cava (IVC), and the hepatic veins to the pulmonary arteries (PA) typically achieved either through an extracardiac (EC) conduit or a lateral tunnel (LT) connection. Although the Fontan procedure is lifesaving for patients with SVHD, this “unnatural” physiology can lead to serious early and late complications in many patients. These comorbidities include obligatory central venous hypertension, pulmonary arteriovenous malformations (PAVM) leading to cyanosis, exercise intolerance, ventricular dysfunction, arrhythmia, thrombus formation, stroke, protein losing enteropathy, exercise intolerance, pleural effusions, and hepatic and/or renal dysfunction \(^1-3\).

Pulmonary arteriovenous malformations (PAVM) are an important cause of progressive cyanosis in patients with a Fontan circulation. PAVMs are abnormal communications that develop between the pulmonary artery and pulmonary veins that bypasses the normal capillary bed impacting gas exchange\(^4\) leading to progressive cyanosis and exercise intolerance\(^4,5\). Complete resolution of PAVM have been achieved post-liver transplantation in the setting of severe liver disease, post-Fontan completion, and after redirection of hepatic venous blood to the affected lung\(^6-9\). These studies stress the importance of symmetric hepatic blood flow to both lungs for the prevention of PAVMs. Symmetric delivery of hepatic venous blood to each lung is dependent on local blood flow dynamics, Fontan geometries, and caval blood flow interactions\(^10-13\).
Cardiac magnetic resonance (CMR) imaging allows for the assessment of vascular anatomy and flow and, when combined with computational fluid dynamics (CFD), can offer patient-specific biomechanical insights improving our quantitative understanding of the complex hemodynamics in Fontan. Numerous CMR-CFD-based studies have been conducted to gain quantitative insights to evaluate Fontan blood flow dynamics\textsuperscript{14-20}. These studies range from estimating the energy loss across the Fontan pathway\textsuperscript{15, 18, 21}, determining optimal hemodynamics\textsuperscript{20}, characterizing hepatic venous flow\textsuperscript{12}, and predicting the non-Newtonian effects of blood in Fontan flow\textsuperscript{22}. CFD-based modeling frameworks are now being extended to perform virtual surgeries to personalize and improve surgical predictability\textsuperscript{10, 23-25}. While these studies have offered important insights into Fontan hemodynamics, shortcomings included small sample sizes, exclusion of hepatic inflow resulting in a limited understanding of local flow dynamics in hepatic-IVC-Fontan confluence, and simulation of only single flow states.

The goal of this study is to perform a comprehensive analysis of hepatic flow distribution (HFD) in a large cohort of LT and EC Fontan patients and quantitatively evaluate the impact of growth-related changes in caval inflow on hemodynamics with particular emphasis on HFD. To this end, we aim to 1) describe the quantitative relationship between the change in SVC-to-IVC inflow (interchangeably referred to as caval inflow) ratio over age, 2) perform CMR-based patient CFD modeling at different SVC-to-IVC flow ratios to quantitatively evaluate the variability of HFD over time, and 3) evaluate the correlations between IVC flow distribution to branch PAs and HFD supported by momentum analysis to delineate the impact of increasing IVC flow on HFD.
Material and Methods

Patient selection – Inclusion and exclusion criteria

Patients after the Fontan operation who had a CMR at Boston Children’s Hospital from 2003 to 2023 were retrospectively reviewed. Inclusion criteria included patients who had an EC or LT Fontan procedure as their primary surgery with non-Fenestrated Fontan or status-post closure. Patients were excluded if they had an interrupted IVC, bilateral bidirectional Glenn procedure, prior history of PAVM, history of thrombosis, or aortopulmonary collateral flow > 40%. This study was approved by the institutional review board at Boston Children’s Hospital.

A random subset of 30 patients with an EC Fontan and 30 patients with LT Fontan were chosen for computational flow modeling. To be included for CFD modeling, patients had to have minimal imaging artifacts, 3D isotropic SSFP imaging, and 2D flow assessment in the SVC, IVC, and branch PAs. Patient specific demographic information and CMR derived flow data are provided in supplementary tables 1 and 2.

Patient-specific anatomy reconstruction from CMR images

Figure 1 illustrates the overall patient-specific workflow for evaluating Fontan flow dynamics for this study. The SVC, IVC, branch PAs, Fontan pathway, and major hepatic vessels were segmented using a threshold appropriate for the blood pool contrast from the 3D isotropic imaging sequences. Segmentation was performed using Mimics 25.0 (Materialise NV, Leuven, Belgium). The geometries were smoothed, and the mesh was constructed using 3-Matic Medical (Materialise NV, Leuven, Belgium) (Figure 1). The STL mesh file was then imported into Fusion 360 (Autodesk, San Rafael, CA), converted to step format, and all vessels were trimmed.
Computational flow modeling

All patient-specific CFD simulations were carried out using the commercial software ANSYS FLUENT V19.0 and 20.0 (ANSYS, Canonsburg, PA) with geometries meshed using ANSYS ICEM. CFD model details such as mesh density for adequate flow resolution, solver methodology that ensured solution convergence for each of these models are provided in the Supplementary Material.

The computational flow domain consisted of the patient’s Fontan pathway, SVC (and the bridging vein if present), left and right PAs, IVC, and the main hepatic veins that drained blood into the Fontan-IVC confluence. The hepatic vessels were included in the analysis to capture the realistic local flow dynamic changes at the hepatic-IVC-Fontan anastomosis as hepatic blood interacted with that from IVC at varying flow rates. The inlets (SVC, IVC, hepatic veins) and the outlets (PAs) were extended to ensure numerical stability during flow computation.

Velocities that corresponded to CMR-measured flow rates were directly applied at the SVC inlets. CMR-measured flow rates at the Fontan baffle were split between IVC and hepatic inflow with 25% of total flow from the hepatic vessels based on previous studies. The PA outlets were defined as pressure boundary conditions with a lumped parameter model coupled at the outlets (Figure 1) that compute outlet pressure based on pulmonary vascular resistance (PVR). The pulmonary vascular resistance (PVR) values were individually tuned for each patient CFD model so that the predicted total flow distribution to the LPA and RPA were consistent with CMR measurements within 5% (Supplementary Tables 1 and 2). This ensured consistency between clinically measured total outflow and the model thus allowing for realistic capture of the inflow, outflow and the local flow dynamics within the Fontan pathway to the lungs. Quasi-steady simulations were performed to solve the governing equations (incompressible Navier-Stokes
equation) with a Quemada non-Newtonian viscosity model\textsuperscript{28} of blood to capture the effect of hematocrit (45\%) and the local shear rate (see Supplementary Materials). HFD and IVC flow distribution, to the lungs were quantified using massless point particles that were uniformly seeded at the hepatic vein and IVC inlets which were passively carried along with the flow to the PA outlets. These particles were tracked, and their flux quantified as they exited the PA outlets \textsuperscript{13, 23} (see Supplementary Material). For each patient model, CFD simulations based on CMR flow data were performed followed by two additional simulations to represent the age-based changes in SVC and IVC inflows.

\textit{Statistical Analysis}

The Shapiro-Wilk test was performed to determine normal distribution of data (See Supplementary data for details). We used the non-parametric Friedman's chi square test for statistical significance among groups because the predicted data on hepatic flow distribution from our CFD analysis (Figure 3) were not normally distributed and involved three time points (or caval inflow ratios) (See Supplementary Figure 2 for Q-Q plots). Friedman's test is thought to be more powerful because it makes fewer assumptions than the parametric ANOVA for skewed distributions\textsuperscript{29}. A P-value of less than 0.05 indicated a statistically significant difference in hepatic flow distribution between the three age groups. Finally, Pearson correlation coefficient (R) was used to establish the correlation between predicted IVC flow distribution to lungs and HFD for each caval inflow ratio with an assumption that an R > 0.5 represents a strong positive correlation (Detailed description of our statistical methodology is provided in the supplementary material).
RESULTS

Impact of age on caval inflows

There were 414 Fontan patients who met inclusion/exclusion criteria and comprised the main retrospective study group. The median age at CMR was 16 [IQR 12, 21] with a range from 2 to 40 years. Supplementary Table 1 details the demographic information of the entire study group. Figure 2A shows the SVC:IVC inflow ratios vs age. SVC:IVC inflow ratios of 2.0, 1.0, and 0.5 corresponded to approximate ages 3, 8, and 15 years old, respectively. There is a non-linear, exponential decline in SVC:IVC inflow ratio from ages 2 to 8, with equal SVC:IVC inflow at around age 8. After age 8, IVC flow predominates but plateaus around age 15 with an SVC:IVC ratio of around 0.5. Accordingly, three simulations were carried out per patient model to predict HFD variation at SVC:IVC ratios of 2.0, 1.0, and 0.5, also adjusting for an estimated age-based corresponding change in total flow\textsuperscript{30-32}. Given that most Fontan procedures occur between ages 3-5 years, this change in SVC:IVC inflow ratio may explain some of the changes in HFD over time (see below). Figure 2B describes indexed total caval inflow (SVC + IVC) indexed to BSA vs age which tends to have less changes as patients get older.

Impact of change in caval inflow on hepatic flow distribution

CFD predictions showed that variations of HFD in response to changes in caval inflow were different in both EC and LT cohorts. In patients with an EC Fontan (n=30), the median CFD-predicted differential pulmonary artery blood flow percentage to the right/left lungs was 54/46%, 53/47%, and 53/47% for caval SVC:IVC ratios of 2.0, 1.0, and 0.5 respectively (Figure 3A). Median differential HFD percentage to right/left lungs were 70/30%, 66/34%, and 65/35% for caval ratios of 2.0, 1.0, and 0.5, respectively (Figure 3B). There was no significant change in
pulmonary artery blood flow distribution or HFD (P=0.46) with changes in age or SVC:IVC flow in patients with an EC Fontan conduit.

For patients with a LT Fontan (n=30), CFD-predicted median differential pulmonary artery blood flow percentage to the right/left lungs was 58/42%, 58/42%, and 57/43% for caval ratios of 2.0, 1.0, and 0.5 respectively (Figure 3C). Median differential HFD percentage to right/ left lungs were 71/29%, 63/27%, and 61/39% for SVC:IVC caval ratios of 2.0, 1.0, and 0.5, respectively (Figure 3D). The change in HFD distribution across three caval inflow ratios was statistically significant (P=0.04). There were no other significant changes in pulmonary artery blood flow in patients with a LT Fontan conduit. These data suggest that the increased proportion of IVC (vs SVC) inflow are driving changes in HFD in patients with a LT Fontan, but not patients with an EC Fontan.

*Strength of positive correlation between IVC flow distribution to PAs and HFD moderately decreases with age*

Twenty-six patients (13 EC, 13 LT) randomly selected from our EC and LT cohorts were further analyzed to determine the correlation between IVC flow distribution to branch PAs and HFD to branch PAs. Strong positive correlations existed between HFD vs IVC flow distribution of r=0.86 (P<0.0001), r=0.73 (P<0.0001), and r=0.63 (P<0.001) for SVC:IVC ratios of 2.0, 1.0, and 0.5, respectively (Figure 4). The strength of the correlation decreased slightly over increased IVC flow (or age). Specific patient examples of momentum analysis with graphical depictions are shown and described in Figures 5-8. The greater momentum of the SVC flow at age ~3 (left panels of Figures 5-8 A), seemed to preferentially divert the IVC flow that seemed to carry the hepatic blood flow (left panels of Figures 5-8 B and C). This flow phenomenon may be attributed to the strong positive correlation between HFD and IVC for SVC:IVC ratio of 2. As IVC flow increases
with age (middle and right panels of Figures 5-8 A), flow disturbance induced by the increased momentum from IVC flow at the IVC-hepatic anastomosis and eventually competing with SVC at Fontan-PA-SVC anastomosis may have contributed to the slight decrease in correlation between HFD and IVC for SVC:IVC ratios of 2 and 0.5 (middle and right panels of Figures 5-8 B and C, Figure 4 B and C) .

Discussion

Blood flow and its interaction with its lumen is a dynamic process that changes with any perturbation caused by either age, growth, disease, or intervention. These hemodynamic concepts are also relevant for the Fontan circulation. With the improved survival of Fontan patients leading and an increase in the worldwide population of surviving Fontan patients with various types of single ventricle anatomy, a broader understanding of how Fontan hemodynamics alters with age can help with the management and prevention of future complications. This study establishes the quantitative shift from SVC dominant to IVC dominant flow as Fontan patients age with an inversion point around age 8. In younger patients with a higher SVC:IVC ratio (2.0), both EC and LT Fontan patients had mild maldistribution of HFD (Figure 3A and C). Patients with a LT had a more favorable “correction” with increased IVC flow (right HFD decreased from 71% → 61%) (Figure 3D). Patients with a EC Fontan did not seen this correction and remained steady across the various flow condition and with increasing age (Figure 3B). This study is the first to show that long-term variations in HFD are impacted by the type of Fontan procedure.

Results from this study show how SVC:IVC inflows into the Fontan pathway change with age and how those changes impact the local hemodynamics and HFD. CMR data collected from a large (n=414) group of Fontan patients revealed a curvilinear change in SVC and IVC flow ratio with age (2/3rd SVC at age~3 transitioning to 1/3rd SVC at age 15+), indicating that the Fontan
inflows can be dynamic at least until adulthood upon which IVC flow dominates (Figure 2). These data are highly consistent with a previous Doppler study by Salim et al., that showed that SVC flow decreased (to 35%) as patients got older. Our CFD model predictions showed that patients with a LT Fontan were more likely to have maldistribution of HFD when SVC inflow dominates (age ~3). This is clinically significant as imbalances to HFD can lead to PAVMs. This maldistribution improved with CFD models with increased IVC flow. EC Fontan physiology was generally more favorable with more symmetric HFD early in life and more consistent even with changes in SVC:IVC flow ratios. These data reinforce the importance of growth-related changes in physiology that should be incorporated while predicting any long-term Fontan hemodynamics.

While it is desirable to have a balanced HFD to prevent PAVMs in Fontan patients, a minimum level of hepatic factor required to prevent PAVMs has not been quantitatively established. Many studies have shown that a complete lack of hepatic blood effluence led to the formation of PAVM. At the same time, there is clinical evidence showing complete resolution of PAVM following redirection of hepatic venous blood to the affected lung. In our patient cohort, while many patients had a balanced HFD (Figure 3), there were some patients with highly skewed HFD especially when SVC inflow dominated the Fontan inflows (age ~3). Our model predictions suggested that HFD tends to achieve some balance with age for these patients consistent with other patient models. These data highlight patient-specificity, how SVC-IVC caval inflow change with respect to age can impact HFD, and the need for personalized planning of Fontan pathways.

Long term outcomes of extracardiac vs lateral tunnel Fontan procedures has been a subject of continuous debate with most decision making highly influenced by individual surgeon choice and institutional preferences. A comprehensive evaluation of power loss utilizing by
Haggerty et al\textsuperscript{15}, revealed no considerable differences between the connection types. The current study provides new quantitative insights with respect to HFD and introduces some concern for early maldistribution of HFD in both Fontan types, but improved balance in patients with a LT Fontan.

Dasi et al identified the caval-offset induced momentum barrier created by the SVC flow being the main factor for unbalanced HFD in extracardiac Fontan\textsuperscript{12}. These findings are highly consistent with our results, especially for age \textasciitilde 3 when SVC flow dominated (Figures. 5-8). Also, the highest skewness in HFD occurred for an SVC-IVC flow ratio of 2 (Age \textasciitilde 3) (Figure. 3) for both EC and LT cohorts highlighting the impact of SVC. Furthermore, our momentum analysis revealed that the potential long-term impact of the SVC momentum barrier, while significant immediately after Fontan completion (Age \textasciitilde 3) diminishes as IVC flow dominated with patient growth (age 8 and 15+, Figures 5-8). These results demonstrate how competing momentum between in the Fontan pathway impacts HFD during the course of time.

Our study has the following limitations. All the simulations were performed using time-averaged flow conditions measured from the MRI with rigid wall assumptions. Rigid wall assumptions were made based on the conclusions from previous study that there was no significant change in HFD due to wall deformation\textsuperscript{38}. The growth of PAs was not accounted for based on the study that reported nonsignificant growth of vessels commensurate with increasing flow\textsuperscript{21, 39}. Fontan flow is known to be transient (e.g.: impact of respiration) and hence, the time-average flow conditions may introduce small quantitative differences. The potential growth and geometry size changes of the LT baffle that can occur with time were also not able to be estimated in this study. Finally, a constant PVR was assumed for all the SVC-to-IVC caval flow ratios while PVR can potentially change over time.
In conclusion, this study described the SVC:IVC flow ratios in a large cohort of patients ranging from 2 to 40 years old, showing the conversion of SVC dominant flow to IVC dominant flow when patients are approximately 8 years old. Using CMR-based patient-specific CFD modeling, both EC and LT Fontan patients had a tendency towards maldistribution of HFD early in line. With increasing IVC inflow with age, patients with a LT had improved HFD distribution, while EC Fontan patients had a relatively consistent HFD. Our analysis provided quantitative insights into the impact of changing caval inflows on long-term hepatic flow distribution in extracardiac and lateral tunnel Fontan types. These data also showed the importance of incorporating SVC:IVC changes over time in CFD modeling toward gaining insights into for long-term hemodynamics of Fontan.

**Supplementary Data**

Supplementary Methods contains detailed description of methodology used in computational flow modeling and statistical analysis.

Supplementary table 1: Demographic details of the extracardiac patient cohort considered in our study. Also shown are IVC, SVC, MRI measured- and CFD predicted flow split.

Supplementary table 2: Demographic details of the lateral tunnel patient cohort considered in our study. Also shown are IVC, SVC, MRI measured- and CFD predicted flow split.
