Highlights

- Acute psychosocial stress increases serum BDNF and cortisol
- Stress-induced cortisol secretion may accelerate the decline of BDNF after stress.
- Chronic stress is linked to lower basal serum BDNF levels
Abstract

Objective: The neurotrophic protein brain-derived neurotrophic factor (BDNF) plays a pivotal role in brain function and is affected by acute and chronic stress. We here investigate the patterns of BDNF and cortisol stress reactivity and recovery under the standardized stress protocol of the TSST and the effect of perceived chronic stress on the basal BDNF levels in healthy young men.

Methods: Twenty-nine lean young men underwent the Trier Social Stress Test (TSST) and a resting condition. Serum BDNF and cortisol were measured before and repeatedly after both conditions. The perception of chronic stress was assessed by the Trier Inventory for Chronic Stress (TICS).

Results: After the TSST, there was a significant increase over time for BDNF and cortisol. Stronger increase in cortisol in response to stress was linked to an accelerated BDNF decline after stress. Basal resting levels of BDNF was significantly predicted by chronic stress perception.

Conclusions: The increased BDNF level following psychosocial stress suggest a stress-induced neuroprotective mechanism. The presumed interplay between BDNF and the HPA-axis indicates an antagonistic relationship of cortisol on BDNF recovery post-stress. Chronically elevated high cortisol levels, as present in chronic stress, could thereby contribute to reduced neurogenesis, and an increased risk of neurodegenerative conditions in persons suffering from chronic stress.

Keywords: brain derived neurotrophic factor (BDNF); cortisol; hypothalamic-pituitary-adrenocortical (HPA) axis; Trier Social Stress Test (TSST)
1. Introduction

Stress-related disorders have emerged as a major health concern in the early twenty-first century and have been linked to altered brain function [1,2]. Acute and chronic stress affects adult neurogenesis and activates a complex interplay of neural and endocrine mechanisms [3,4]. Glucocorticoids (GCs), as a key part of the body's stress response system, and brain-derived neurotrophic factor (BDNF), with its multiple roles in the nervous system, influence adult neurogenesis through their dynamic interactions in the context of acute and chronic stress [5,6].

The neurotrophic protein BDNF plays a pivotal role in brain function throughout life [6]. BDNF protects existing neurons and synapses of the central nervous system (CNS) [7]. In the neurogenesis BDNF acts through the family of high-affinity tyrosine kinase receptors i.e. the tropomyosin receptor kinase B (TrkB) receptor [8,9]. In addition to these direct functions on neuronal structure, BDNF is known to contribute to the regulation of eating behaviour and physical activity [9]. In the hippocampal, BDNF is a key molecule related to learning and memory [6]. BDNF physiologically decreases with normal ageing [10] and the development of cognitive impairment is affected by chronic stress [11]. Of note, altered BDNF were detected in different diseases, including depression [12] and Alzheimer’s disease [13].

Different studies suggested that both acute and chronic stress could affect BDNF [6]. With regard to the acute stress, BDNF increases have been observed in healthy adults in response to acute psychosocial stress in the laboratory using the internationally established Trier Social Stress Test [14–16]. In animals, chronic stress caused a reduction in neuronal Bdnf mRNA expression [17]. In line, reduces BDNF levels were reported in hospital employees who were psychologically stressed through their work [18]. Thus, BDNF is a stress-dependent factor [19].

Of note, BDNF appears to interact with the hypothalamic-pituitary-adrenocortical (HPA)-axis, one of the major physiological stress systems. BDNF is expressed in the hypothalamus's paraventricular nucleus (PVN) [20], the upstream regulator of HPA-axis activity. In this brain...
area, corticotrophin-releasing hormone (CRH) is regulated in response to internal and external stimuli [21]. Glucocorticoid action on glucocorticoid receptors in the PVN are crucial components of the negative feedback loop that controls HPA-axis activity [22]. Of notice, dysregulation of glucocorticoid receptor function not only leads to a disturbed HPA-axis feedback loop with an increase in CRH-expression but also causes an increase of hypothalamic BDNF [19]. This suggests a causal suppressive impact of glucocorticoid signaling on BDNF expression or release. Though, the relation between glucocorticoids and BDNF appears to be bi-directional, as BDNF injections also raised CRH levels and stimulated the HPA-axis [23]. How these mechanistic findings translate into humans is still not fully clear.

The HPA-axis regulates the acute and chronic stress response through the secretion of glucocorticoids, the most important of which is cortisol [5]. While it is well established that BDNF and cortisol levels increase in response to acute stress [6], how they interact under acute stress is less clear. As a possible mechanism, Suri & Vaidya [24] described that stress-induced cortisol secretion has regulatory effect on BDNF secretion.

Human studies have shown stress-induced increases in both cortisol and BDNF in response to a psychosocial stressor [14–16]. However, possible interactions between BDNF and cortisol dynamics are not well-established. The three previous studies on the topic had varied methodologies. Factors like a single post-stress blood sample [14,15], salivary cortisol measurements [15], and no distinct analysis of BDNF/cortisol responses to stress and recovery [14–16] make it hard to definitively determine their relationship.

Therefore, we aimed to clarify the patterns of BDNF and cortisol stress reactivity and recovery under the standardized stress protocol of the TSST with repeated blood samples to determine cortisol and BDNF in parallel. Based on the previous studies investigating BDNF and cortisol stress reactivity [14–16], we hypothesized stress-induced increase of BDNF and cortisol following the acute psychosocial laboratory stressor (Hypothesis 1). Given the postulated
regulatory effect of stress-induced cortisol on BDNF secretion [24], we hypothesized a negative association between patterns of cortisol stress reactivity and BDNF stress recovery (Hypothesis 2). In view of the relationship between chronic stress and BDNF levels [17,18], we hypothesized that chronic stress perception would be a predictor of basal resting levels of BDNF (Hypothesis 3).
2. Methods

2.1 Study participants

Twenty-nine healthy male individuals were recruited via electronic tendering (e-tendering) and notice boards at the Johannes Gutenberg University Mainz. Study criteria were assessed by telephone interview using the full Structured Clinical Interview (SCID; [25]) for the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV, [26]). Exclusion criteria were acute or chronic medical illness, mental disorders, medication or substance use, stressful life events in the past six months, being younger than 18 or older than 35, and smoking more than ten cigarettes per day. Due to known age and gender specific differences in BDNF levels [27,28], only male participants aged between 18 and 35 years were included. The mean age of the participants was 24.34 ± 4.08 years of age with a body mass index (BMI) of 22.94 ± 1.61 kg/m². A detailed description of all participants, including demographic data and psychological status is given in Table 1. The study protocol was approved by the local Ethics Committee of the Landesärztekammer Rheinland-Pfalz, Germany (No#2019-14188).

2.2. Study design

Participants underwent two different conditions, stress and resting, on separate days within a seven-day period. Both conditions started between 2:00 p.m. and 5:00 p.m., and the order of testing was randomized. Participants were asked to refrain from eating, drinking, and smoking before and during the two-hour test session. To avoid a pain-induced release of BDNF and cortisol, the intravenous cannula was inserted 45 minutes before the first blood sample was taken. The experimental protocol began with a 15-minute pre-session, which included the collection of two blood samples. Participants then underwent two 15-minute conditions: stress and rest. The stress condition was the Trier Social Stress Test (TSST), following the Kirschbaum et al. [29] protocol. It consisted of three sections: preparation, interview, and a calculation task, with each section lasting 5 minutes. In contrast, during the resting condition, participants were given the opportunity to read magazines. Cognitive appraisal was assessed
three minutes after the start of each condition using the Primary Appraisal Secondary Appraisal (PASA) scale [30]. In addition, participants’ self-reported perception of stress was measured immediately after both conditions using the visual analogue scale (VAS). After completing the stress and resting conditions, participants remained in a supine position on a bed for 105 min, during which nine blood samples were taken at different time points: +1, +5, +10, +20, +30, +45, +60, +75, and +105 minutes.

2.3 Blood analytics

Blood samples were collected in serum monovettes (S-Monovette® 7.5 ml Z, Sarstedt, Nümbrecht, Germany). After blood collection, the monovettes were left at room temperature for 30 min to allow the blood to coagulate. The monovettes were then centrifuged at 2500 g for 10 min at 20°C, divided into aliquots and stored at -80°C. BDNF concentration were determined by enzyme-linked immunosorbent assay (ELISA) (Human Free BDNF Quantikine ELISA Kit–R&D Systems Europe, Ltd. Abingdon, United Kingdom). Serum cortisol concentrations were quantified using a commercially available enzyme-linked immunosorbent assay (ELISA) kit (IBL International GmbH, Germany).

2.4 Questionnaires

The Beck Depression Inventory (BDI; [31]) was used to assess the severity of depression. The inventory is based on 21 items with a four-point rating scale from 0 to 3. The total score ranges from 0 and 63, with a higher total score indicating more depressive symptoms. The Perceived Stress Scale (PSS; [32]) measures the level of stressful situations in one’s life during the previous month. The questionnaire consists of 14 items on a 5-point scale ranging from 1 ‘never’ to 5 ‘very often’. The Global Severity Index (GSI) of the Symptom Checklist-90-Revised (SCL-90-R; [33]) was used to assess a person’s perceived impairment from physical and psychological symptoms of a person. The screening subscale (SCSS) of the Trier Inventory for Chronic Stress (TICS), developed by Schulz et al. [34], was used to assess the level of
chronic stress experienced in the previous three months. Eleven items have to be answered on a five-point rating scale ranging from ‘never’ (0) to ‘very often’ (4).

2.5 Statistical analysis

A power analysis calculated with the G*power program (version: 3.1.9.2.) [35] showed that to expect a medium effect size of Cohen’s $f = .25$ for the outcome measure of BDNF, using a two-way MIXED ANOVA for repeated measures as the statistical test to prove interaction of within-factor time (measurement points -1, +1, +5, +10, +20) and within-factor condition (stress vs. resting) with a significance level of $p = .05$ and power of 80% ($1-\beta = .80$), a total sample size of $n = 22$ participants would be required. The BDNF and cortisol data were analyzed according to the normality of the distributions and, in case of non-normally distributed data, were subjected to logarithm naturalis transformations. Statistical analysis was performed with SPSS Statistics version 27 (IBM, Chicago, IL, USA).

For the BDNF and cortisol response, the area under the curve with respect to increase (AUC$_I$) and the delta between peak and baseline (Δ Peak-Base) were calculated [36,37]. All parameters (PASA, VAS, Cortisol-AUC$_I$, & Cortisol Δ Peak-Base) were analyzed by two-factorial MIXED ANOVA for repeated measurements with the within-factor condition (stress vs. resting) and within-factor time.

For the specification of the BDNF and cortisol stress reactivity and recovery during the stress condition, the area under the curve with respect to increase and decrease (AUC$_I$/AUC$_D$) were calculated using the formulas of Pruessner et al. [36]. Stress reactivity was defined as the incremental area under the curve from baseline to peak value. Stress recovery was defined as the decremental area under the curve from the peak value to the last measurement point. Both areas under the curve were calculated individually for each subject based on the individual peak values. The association between BDNF and cortisol stress reactivity and recovery was tested using Pearson’s correlation test.
Regression was calculated to predict the influence of the subjective chronic stress on the basal serum BNDF concentration (-1 minute time point) of the resting and stress condition.
3. Results

**BDNF responses to acute stress compared to rest**

BDNF levels were comparable before both the stress and the resting condition (-1min: \( t(28) = .433, p = .67 \), Figure 1). ANOVA results indicated a significant effect of time over the five measurement points \( (F(2.922, 81.820) = 8.110, p \leq .001, \eta^2 = .225) \). There was a significant main effect of condition on BDNF concentration, with higher values in the stress induction condition compared to the resting condition \( (F(1, 28) = 6.506, p \leq .05, \eta^2 = .189) \) and a significant interaction effect time x condition \( (F(4, 112) = 5.532, p \leq .001, \eta^2 = .165) \). In line, peak concentrations in BDNF \( (t(28) = 4.536, p \leq .001, d = .84) \), the absolute change in BDNF \( (t(28) = 2.514, p \leq .01, d = .47) \), and the incremental AUC \( (t(28) = 2.555, p \leq .01, d = -.47) \) were higher in the stress condition compared to the resting condition.

**Cortisol responses to acute stress compared to rest**

Resting serum cortisol was comparable between the two study days (-1min: \( t(27) = -.089, p = .93 \), Figure 2). There were significant time \( (F(3.691, 99.653) = 63.186, p \leq .001, \eta^2 = .701) \), condition \( (F(1, 27) = 40.111, p \leq .001, \eta^2 = .598) \), and time x condition effect \( (F(4.125, 111.386) = 16.947, p \leq .001, \eta^2 = .386) \) on serum cortisol. Peak cortisol \( (t(27) = 7.831, p \leq .001, d = 1.47) \), the absolute change in cortisol \( (t(27) = 6.736, p \leq .001, d = 1.27) \), as well as the incremental AUC \( (t(27) = 5.870, p \leq .001, d = 1.11) \) were higher in the stress condition compared to the resting condition.

**Psychological responses to stress induction versus rest**

Analyses of the two questionnaires showed that the TSST was successful in inducing stress: male participants showed significantly higher scores in the VAS \( (t(28) = 7.633, p \leq .001, d = 1.41) \) and on the tertiary scale ‘stress index’ of the PASA \( (t(28) = 8.903, p \leq .001, d = 1.65) \).
Association between BDNF and cortisol stress reactivity and their recoveries

Regarding to the relationship between BDNF and cortisol reactivity/recovery patterns, a negative significant correlation was found between cortisol stress reactivity and BDNF stress recovery ($r (26) = -.39$, $p \leq .05$). No significant correlation was found between BDNF and cortisol stress recovery nor between BDNF stress reactivity and cortisol stress reactivity/recovery (see Table 3).

Influence of chronic stress on basal BDNF

Chronic stress is a significant predictor of basal serum BNDNF concentrations in both conditions (stress: $F_{(1,27)} = 4.320$, Adj. $R^2 = .14$, $p \leq .05$; resting: $F_{(1,27)} = 4.483$, Adj. $R^2 = .14$, $p \leq .05$). A higher chronic stress is associated with an increase in basal serum BDNF concentration and vice versa.
4. Discussion

We assessed the responses in BDNF and cortisol stress to a standardized stress task as well as their recovery. The applied stressor was sufficient to induce robust increases in BDNF and cortisol, which was not the case in the control condition. Interestingly, a strong cortisol response to stress was linked to an accelerated BDNF decline post-stress. Furthermore, higher chronic stress levels were linked to lower basal BDNF.

The stress-induced increases in BDNF and cortisol in our current study are well in line with earlier studies that also applied the TSST [14–16]. The activation of the acute stress system activation triggers a cascade of physiological changes, including the release of the stress hormone cortisol and the upregulation of BDNF. The latter likely serves as a neuroprotective mechanism to maintain brain health and cognitive function during stress [6].

The most important finding of our current study is the link between the cortisol response to stress and the subsequent BDNF recovery. This supports the hypothesis of Linz et al. [15] of an antagonistic relation between cortisol and BDNF in response to stress.

While animal models demonstrated an increase in both cortisol and hippocampal Bdnf mRNA expression in response to short-term stressors [38]. However, studies in animals furthermore demonstrated that elevated stress cortisol levels decrease hippocampal Bdnf mRNA expression [39,40]. This mechanistic data together with our findings and those from Linz et al. [15], highlight a dynamic relationship between cortisol and BDNF during stress. Initially, both factors increase in response to stress. Yet, as the stress response concludes, GC signaling could suppress BDNF. This pattern suggests an adaptive mechanism: an initial boost in BDNF could enhance cognitive function and neural plasticity during stress, while its subsequent suppression by GC signaling may help conserve energy and return the system to a baseline state once the stressor has passed [4,5,24].
In line with this hypothesis, we found high chronic stress perception to be linked to low basal serum BDNF levels. A comparable cross-sectional result of lower basal BDNF levels and higher psychological job stress was also observed in hospital employees [18]. In rodents, repeated restraint stress over 2-3 weeks reduced hippocampal Bdnf [17]. McEwen's allostatic load model suggests that ongoing stress harms brain structures and overburdens the stress system, leading to prolonged high cortisol levels [1,21]. These repeated elevations in cortisol could decrease BDNF, affect neurogenesis, and contribute to neurodegenerative diseases [41]. Understanding the effects of chronic stress on BDNF may help to develop interventions and therapeutic strategies to mitigate the negative effects of chronic stress on the brain and overall well-being [42,43].

A major strength of this study is the within-subjects design using the standardized and reliable psychosocial stress test (TSST) and a resting control condition regarding to the circadian rhythm of BDNF [44]. In addition, there was a frequent assessment of serum BDNF and cortisol to accurately measure stress-induced dynamics, including peaks and recovery processes.

However, the present study has some limitations. Given the known age- and gender-specific differences in BDNF levels [27,28], we limited our study to young male participants. Thus, further research need to test our findings in women and older persons. Finally, in the present study serum BDNF levels were measured which may not necessarily fully reflect the regulation of BDNF in the hippocampus [45–47].

In conclusion, the present study showed that acute psychosocial stress increases serum BDNF and cortisol. The rise in cortisol appears to regulate the decline in BDNF post-stress. Chronic stress could lead to significant changes in BDNF in the circulation and presumably also in the brain. This could contribute to reduced neurogenesis, and an increased risk of neurodegenerative conditions in persons suffering from chronic stress. This could be the basis
for interventions that can offset the detrimental effects of chronic stress on BDNF with possible long-term benefits for brain health and overall well-being.
