Abstract:

Background: Post-stroke upper limb (UL) motor improvement is associated with adaptive neuroplasticity and motor learning. Both intervention-related (including provision of intensive, variable, and task-specific practice) and individual-specific factors (including the presence of genetic polymorphisms) influence improvement. In individuals with stroke, most commonly, polymorphisms are found in Brain Derived Neurotrophic Factor (BDNF), Apolipoprotein (APOE) and catechol-O-methyltransferase (COMT). These involve a replacement of cystine by arginine (APOEε4) or one or two valines by methionine (BDNF: val^{66}met, COMT: val^{158}met).

However, the implications of these polymorphisms on post-stroke UL motor improvement specifically have not yet been elucidated.

Objective: Examine the influence of genetic polymorphism on post-stroke UL motor improvement.

Design: Systematic Review and Meta-Analysis

Methods: We conducted a systematic search of the published literature in English language of using standard methodology. The modified Downs and Black checklist helped assess study quality. We compared change in UL motor impairment and activity scores between individuals with and without the polymorphisms. Meta-analyses helped assess change in motor impairment scores based upon a minimum of two studies per time point. Effect sizes (ES) were quantified.
based upon the Rehabilitation Treatment Specification System as follows: small (0.08–0.18), medium (0.19–0.40) and large (≥0.41).

Results: We retrieved 10 (four good and six fair quality) studies. Compared to those with BDNF val<sup>66</sup>met polymorphism, meta-analyses revealed lower motor impairment scores (large ES) in those without the polymorphism at intervention completion (0.5, 95% CI: 0.11-0.88) and at retention (0.58, 95% CI: 0.06-1.11). Presence of CoMT val<sup>158</sup>met polymorphism had similar results, with higher levels of improvement in impairment (large ES ≥1.5) and activity scores (large ES ranging from 0.5-0.76) in those without the polymorphism. Presence of APOE ε4 form did not influence UL motor improvement.

Conclusion: BDNF val<sup>66</sup>met and COMT val<sup>158</sup>met polymorphisms negatively influence UL motor improvement in impairment and activity scores.

Registration: https://osf.io/wk9cf/
Introduction

Stroke continues to be a leading cause of adult morbidity in the United States. One of the most disabling aftereffects of a stroke is the presence of upper limb (UL) hemiparesis. A large proportion of stroke survivors present with UL sensorimotor impairments on the paretic side, reduced independence in performance of daily life activities (ADL) and restricted participation. Along with spontaneous recovery mechanisms, motor improvement of the paretic side enabling successful task-performance is attributable to adaptive neuroplasticity and motor learning.

Successful task-performance entails an interaction of the individual, environment, and the task to be performed. The role of the environment and factors influencing task-practice have been extensively studied. Recently, there is a renewed focus on the role of individual-specific characteristics such as levels of motivation, mood and the role of biomarkers. Bernhardt et al defined biomarkers as “indicators of disease state that can be used clinically as a measure reflecting underlying molecular and cellular processes that may be difficult to measure directly in humans and could be used to predict recovery or treatment response.” Biomarker studies within the realm of neurorehabilitation include those based on biology (e.g., genetics), structural and/or imaging and neurophysiological markers of central nervous system excitability and electrical activity.

The role of imaging-based biomarkers of structural and functional corticospinal tract connectivity alone or in combination with neurophysiological markers (e.g. motor evoked potential amplitude) has been extensively studied. The role of genetics-based biomarkers is
slowly gaining prominence, with studies focusing on single nucleotide polymorphisms (SNPs). These SNPs can alter the basic functioning in cellular and molecular processes and tend to influence functional improvement produced by environmental interaction and in response to rehabilitation interventions. Genetics-based biomarkers identified as pertinent to stroke recovery include SNPs in brain-derived neurotrophic factor (BDNF), Catechol-o-methyltransferase (COMT) and Apolipoprotein (APOE).

An activity dependant neurotrophin important for neuroplasticity and protection after injury, BDNF facilitates synaptic transmission and long-term potentiation important for motor learning. A common SNP that occurs in BDNF is substitution of one or two valines at codon 66 with methionine due to substitution of adenine in place of guanine at nucleotide 196. The polymorphism reduces activity-dependent BDNF release, and results in altered neuroplasticity and learning in healthy controls and after a stroke.

The COMT enzyme helps degrade and thus influences the availability of Dopamine in the central nervous system. Dopamine can influence post-stroke motor learning and improvement. A commonly observed SNP results in a change from valine or methionine at codon 158 (in the membrane form) and codon 108 in the soluble form, which results in a 3-4 fold decrease in COMT activity. The role of COMT polymorphism has primarily been assessed on motor learning in Parkinson’s disease and severe Schizophrenia. Given that COMT is found in areas essential for motor learning, such as striatum and motor cortex, the effects of COMT polymorphism on post-stroke motor improvement need to be addressed.
Although involved in lipid transport between cells, APOE helps modulate neuronal repair and regeneration of nervous tissue. One of the alleles of APOE is the Epsilon-4 form (ε4) with arginine at positions 112 and 158 in place of cystine. Presence of APOE-ε4 can cause reduced hippocampal volume and cortical thickness, cognitive impairments and lower recovery levels after traumatic brain and spinal cord injuries. After a stroke, previous meta-analyses revealed lower improvement after sub-arachnoid hemorrhage in those with the ε4 form, but no association with improvements after ischemic strokes. In both studies, motor improvements were assessed using generic scales such as the modified Rankin Scale (mRS). Improved scores in assessments such as the mRS does not specifically represent UL motor improvement. As presence of cognitive impairments influence UL motor improvement, the effects of the APOE-ε4 form on post-stroke UL motor improvements needs to be systematically evaluated.

The role of genetic polymorphisms has previously been reviewed. These studies were either narrative reviews or meta-analyses including global stroke outcomes like National Institutes of Health Stroke Scale and/or mRS. Post-stroke UL motor improvement continues to remain variable and less than optimal in many cases. Evaluation of whether and to what extent genetic polymorphisms influence the extent of improvement may help explain some of the observed variability. Using a systematic review and meta-analysis, we examined the influence of genetic polymorphisms on UL motor improvement. The question guiding our review was “In individuals with post-stroke UL hemiparesis, does the presence, compared to the absence of genetic polymorphisms, influence motor improvement?” Preliminary results have previously appeared as an abstract.
Methods

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The protocol was registered on the Open Science Framework (https://osf.io/wk9cf/).

We searched the literature for studies involving human subjects published in English between the years 2000 and 2023. The last search was conducted in September 2023. Key search terms used included: stroke, cerebrovascular accident, upper limb, arm, rehabilitation, impairment, activities of daily living, recovery, polymorphisms, gene*, neuroplasticity, and motor learning. Databases searched included: PubMed and ISI Web of Science and the Google Scholar repository. We included studies that used clinical assessments of UL motor impairment and/or ADL and provided data for individuals with and without polymorphisms. We excluded studies focusing exclusively on lower limb or on only cognitive outcomes. We also excluded other reviews, although we searched the reference lists of these excluded reviews for pertinent citations. To identify additional relevant articles, we also searched reference lists of each retrieved study.

Data Abstraction

We grouped the retrieved articles according to the polymorphism examined. We developed and used a data abstraction form to extract data from the selected articles. Data were initially extracted by RTM, CR and KMS. The first author (SKS) then verified that all relevant data were obtained from the selected articles. The extracted data included details about
chronicity, distribution of sample based upon those with and without polymorphism, details
about the intervention, outcomes used to assess change and the study results.

Study quality assessment

We assessed the quality of the selected articles using the modified version\(^{46}\) of the
reliable and valid Downs and Black (D&B) checklist.\(^ {47}\) The D&B checklist can be used to assess
the quality of both randomized and non-randomized study designs. The total scores of this
assessment and PEDro scale are highly correlated in studies involving post-stroke participants.\(^ {48}\)
According to available guidelines,\(^ {49}\) we classified the scores as “excellent” (score 24-28), “good”
(score 19-23), “fair” (score 14-18), or “poor” (score ≤ 13). The quality of each study was
independently evaluated by RTM, CR and KMS, with discrepancies, if any, resolved by SKS and
CLL.

Risk of Bias

The risk of bias (ROB) was estimated using the Cochrane ROB tool\(^ {50}\) and ACROBAT-
NRSI (A Cochrane Risk Of Bias Assessment Tool: for Non-Randomized Studies of
Interventions)\(^ {51}\) for randomized and non-randomized studies respectively. The Cochrane ROB
tools assesses the following domains: sequence generation, allocation, concealment, blinding of
participants, personnel and outcome assessors, incomplete outcome data, selective outcome
reporting, and other sources of bias. For each domain, we assigned a judgment: Yes - indicating
low ROB, No - indicating a high ROB, and Unclear - indicating unclear or unknown ROB where
reported details were insufficient to reach a conclusion. The ACROBAT-NRSI tool assesses bias
that can arise because of confounding, study participant selection, intervention measurement,
departures from intended interventions, missing data, outcome measurement and reported result selection.

Statistical analyses

Descriptive statistics of the study populations were calculated as percentages of the total sample. When an article reported the effect of a particular polymorphism at both the motor impairment and activity limitation levels, they were considered separately. Meta-analyses (RevMan 5) examined differences in Fugl-Meyer (FM) scores in groups with and without polymorphism. Pooled effects of the polymorphisms were quantified with standardized mean differences.\textsuperscript{52} If at least two studies reported the effects of the polymorphism on change in FM scores, we included them in the meta-analysis.\textsuperscript{53,54} I\textsuperscript{2} scores helped assess heterogeneity.\textsuperscript{55}

Given that a variety of interventions were employed in the different studies, we used the random effects models (irrespective of I\textsuperscript{2} values). Effect sizes were categorized as small (0.08 - 0.18), medium (0.19 - 0.40) and large (≥0.41), in accordance with the Rehabilitation Treatment Specification System recommendations.\textsuperscript{56} Sensitivity analysis was carried out to assess the effect of provision of rehabilitation interventions. We conducted an additional analysis excluding any study that did not report details of rehabilitation interventions provided.

Results

The search and selection results are shown in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram. In total, 319 citations were identified through database and registry searches (Figure 1). After removing duplicates, 187
citations were screened, of which 16 were excluded. We sought 116 reports for retrieval and assessed 31 for full text eligibility, which were experimental studies including outcomes related to rehabilitation. We further excluded 21 studies, as they included lower limb and/or gait outcomes or used generic measures such as the mRS, NIHSS and Barthel Index. Ten articles assessing the effects of genetic polymorphisms on UL motor impairment and ADL performance were included in the qualitative synthesis (Figure 1). The reference lists of these ten articles did not yield any additional citations.

Out of the 10 studies, eight examined the influence of BDNF val<sup>66</sup>met and two addressed the effects of COMT val<sup>158</sup>met polymorphisms. Two of the eight studies assessing the effects of BDNF val<sup>66</sup>met polymorphism additionally examined effects of APOE ε4 polymorphism. Six<sup>23</sup>,<sup>57</sup>-<sup>61</sup> of the eight articles addressing effects of BDNF polymorphism had available FM scores assessed at the end of the intervention to be used for a meta-analysis. Two studies<sup>59</sup>,<sup>60</sup> also included a retention assessment, with that data being included for a second meta-analysis.

**Insert Figure 1 here**

**BDNF val<sup>66</sup>met polymorphism**

In total, 598 individuals (59.2% men, 40.8% women) sustaining a stroke participated in the eight studies included in the qualitative analysis. The average age of the participants (mean ± SD) was 58.4 ± 3.2 years. A greater proportion of participants had sustained ischemic strokes (79.7%) compared to hemorrhagic strokes (20.3%). The distribution of the more-affected side was almost equal (50.7% right, 49.3% left). Four<sup>57</sup>,<sup>61</sup>-<sup>63</sup> of the included studies were ranked as *good* and the remaining six<sup>23</sup>,<sup>58</sup>-<sup>60</sup>,<sup>64</sup>,<sup>65</sup> *fair* (*Supplementary Table 1*). Participants were either in
the acute\textsuperscript{57-60,64} or chronic\textsuperscript{23,61} stage post-stroke. All participants had moderate-to-severe\textsuperscript{66} UL motor impairment (FM score $\leq$49/66).

\textit{Insert Table 1 and figure 2 near here}

Table 1 presents a summary of studies evaluating the effects of BDNF polymorphism with a focus on sample size, type and dose of rehabilitation provided (if any), main outcomes and results. The sample size used for the Meta-analysis was 295 (no polymorphism: 101, polymorphism: 194). Analysis revealed a large (0.50, 95\% CI: 0.11 - 0.88, $p = 0.01$, $I^2 = 54\%$, random effects model; Figure 2) effect size at the end of the intervention period for improvement in UL FM scores in those without compared to those with the polymorphism. At retention testing, the sample size used was 79 (no polymorphism: 19, polymorphism: 60,). We found a similar large effect size (0.58, 95\% CI: 0.06 - 1.11, $p = 0.03$, $I^2 = 0\%$, random effects model; Figure 3).

\textit{Insert Figure 3 near here}

In addition to UL FM scores, other assessments at the body structure and function level included use of functional magnetic resonance imaging (fMRI), diffusion tensor imaging (DTI) and MRI. In terms of fMRI outcomes, lower ipsilesional activation volume and percentage signal change were noted in individuals with the Met alleles as compared to the Val homozygous individuals\textsuperscript{23}. Use of DTI revealed differences in radial and axial diffusion\textsuperscript{59} and fractional anisotropy\textsuperscript{60} between individuals with and without met alleles. Individuals with met alleles also had greater cerebral atrophy on MRI\textsuperscript{62}. 

insert table and figure here
Sensitivity analysis included an additional meta-analysis being conducted with data from five studies included in this analysis. The only study excluded provided no details on whether and if so, how many sessions of any form of rehabilitation were provided to the participants. The sample size used for this Meta-analysis was 260 (no polymorphism: 91, polymorphism:169). Analysis revealed a large (0.43, 95% CI: 0.01 - 0.86, p = 0.046, I² = 57%, random effects model; Figure 4) effect size at the end of the intervention period for improvement in UL FM scores in those without compared to those with the polymorphism.

Insert_Figure_4_near_here

APOEɛ4 Polymorphism

Table 2 presents a summary of studies evaluating the effects of APOEɛ4 and COMT val met polymorphism. Two (good quality) of the eight studies examining the effects of BDNF val66met polymorphism also assessed the effects of APO ɛ4 polymorphism. These two studies included a total of 260 participants (61.5% men, 38.5% women). A greater proportion of participants had sustained ischemic strokes (83.4%) compared to hemorrhagic strokes (16.7%). The distribution of the more-affected side was equal (50% right, 50% left).

Both studies used the Wolf Motor Function Test - timed test (WMFT-tt) as the primary outcome. No differences were noted between individuals with and without the polymorphism on WMFT-tt scores (Table 2A). In addition, groups did not differ on the amount of change seen in UL FM scores and self-reported levels of UL quality (assessed using the Motor Activity Log) or in the amount of cerebral atrophy noted between groups.

Insert_Table_2_near_here
**COMT val<sup>158</sup>met Polymorphism**

Two fair quality studies including 157 participants (59.7% men, 40.3% women) examined the influence of COMT val<sup>158</sup>met polymorphism (53: no polymorphism, 104: polymorphism). A greater proportion of participants had sustained ischemic strokes (83.8%) compared to hemorrhagic strokes (16.2%). The distribution of the more-affected side was 46.8% right side, 51.9 %, left side and 1.3% of the participants had bilateral strokes. The studies used either the UL section of the Rivermead Motor Assessment (RMA) or the FMA.

Compared to those with met<sup>158</sup>met, participants with val<sup>158</sup>met allele (ES = 0.51) or val<sup>158</sup>val (ES = 0.76) distribution had greater recovery with large effect sizes on the UL section of the RMA, at the end of the intervention period. Similar results were obtained for the FMA. Individuals with val<sup>158</sup>val distribution had greater recovery on the FMA at the end of the intervention period (ES = 2.69), and at 3 (ES = 1.51) and 6 months (ES = 1.98) retention testing. In addition, participants without the polymorphism improved more on other components of the RMA scores including gross function, leg, and trunk function and higher FIM scores.

**Risk of Bias:**

Overall, the risk of bias was low for all studies (Supplementary Figure 1, Supplementary Table 2), except one. The ROB for this one study could not be ascertained for the domains of measurement of interventions and departures from intended interventions, as information on whether the participants received any intervention or not was missing.
Discussion

Results from this systematic review and meta-analysis showed that the presence of some genetic polymorphisms negatively influence post-stroke UL motor improvement. The meta-analyses revealed that BDNF polymorphism negatively impacted UL motor improvement, immediately after the end of the intervention period as well as at retention testing. Overall, majority of the studies had low risk of bias, which lends further credence to these results. Sensitivity analyses revealed that results continued to remain significant even with the exclusion of the study where information on some domains of bias was not available.

These results are in agreement to those found previously, and extend those findings more specifically to UL motor improvement and not just general recovery from a stroke. We also found that while APO ε4 polymorphism does not influence UL motor improvement, presence of COMT val\textsuperscript{158}met polymorphism has a negative impact. Our results for APO ε4 agree partially with those found previously, and go beyond those results by focusing on UL motor improvement. To our knowledge, this is the first review which has systematically investigated the effects of COMT polymorphism on post-stroke UL motor improvement.

Study Quality Assessment

Of the ten articles included in the review, four\textsuperscript{57, 61-63} were ranked as ‘good’ and the remaining six\textsuperscript{23, 58-60,64,65} ‘fair’. We did not find any articles that could be categorized as being of ‘poor’ quality. However, we also did not have any articles that were ‘excellent’ in quality. We used the modified D&B checklist in this review, as both randomized and non-randomized study
designs were included. The modified D&B checklist score includes an assessment of internal and external validity, reporting standards and sample size. Commonly non-reported details across studies in this review include information on external validity (three questions) and on power/sample size analysis. Inherent word limitations in manuscript length may often preclude exclusion of such information in the main text. It is suggested that such information may be reported at least as supplementary material to provide a better overview of the rationale behind participant selection in the studies.

Interventions used and number of sessions

A variety of interventions were used amongst the various studies included in the review. The interventions used included the use of rTMS along with traditional physical (PT) and occupational therapy (OT) sessions, provision of traditional PT and OT sessions alone virtual reality platform along with robotic assistive devices, commercial gaming solution (i.e., Nintendo Wii), modified constraint induced movement therapy, and task-oriented UL training. No details were provided for two studies. The above-mentioned interventions were delivered at different intensities. Time spent in therapy was the most common metric used to denote intensity in the included studies. Time spent in therapy was either 60 minutes/day, 90 minutes/day (outpatient rehabilitation phase) or three hours/day. Therapy was provided for 10 sessions over 2 weeks, 2-3 weeks or 30 sessions. Information on exact number of sessions was not provided for the other studies.

Although time spent in therapy is one metric of intensity, other metrics include numbers of repetitions as well as "amount of physical and/or mental work put forth by the client".
Previous work involving healthy controls with BDNF polymorphism has shown that employing a high number of repetitions (about 800 repetitions/session) for about five days can cause significant changes in short-term plasticity even in those with the polymorphism. The minimal number of repetitions/session in individuals with BDNF and other polymorphisms that have also sustained a stroke are currently unknown. Approaches similar to those used previously could be employed to estimate the minimal number of repetitions to achieve a plateau in motor performance in a single session. Whether using a fixed number of repetitions results in better UL motor improvement in post-stroke individuals with polymorphisms remains to be estimated.

Outcomes used to assess improvement

A variety of outcomes were used to assess the effects of the different polymorphisms. At the body structure and function level, in addition to the FMA, the Rivermead Motor Assessment, MRI, fMRI and diffusion tensor imaging (DTI) were used. At the activity level, Box and Blocks Test, Wolf Motor Function Test and Motor Activity Log helped specifically assess UL activity performance, while outcomes including Barthel Index and Functional Independence measure helped assess general activity performance. All the selected outcomes have well established psychometric properties and measures including the FMA, Functional Independence Measure, Motor Activity Log, Rivermead Motor Assessment, and Wolf Motor Function Test are amongst recommended measures. However, no study used any assessment at the participation level. Hence the effects of the polymorphism at the participation level have not yet been assessed. If select core measures such as those recommended by previous publications are used, the effects across the different levels of the ICF could be better understood. In addition, the UL part of the FM does not account for the use of altered movement patterns. It is currently
unknown whether individuals with genetic polymorphisms use compensatory movement patterns for task completion.

Influence of ethnicity

Majority of the studies in this review emerged from Asia, particularly from South East Asia, with only four studies\textsuperscript{23,61-63} being conducted outside Asia. Amongst these four studies, three\textsuperscript{23,61,62} had detailed demographics available on ethnicity of the participants. Individuals belonging to Asian Ethnicity already have poor outcomes after a stroke.\textsuperscript{77} There are some reports that individuals of Asian Ethnicity tend to receive less rehabilitation services compared to individuals from a Caucasian ethnicity and have higher rates of hospital readmission.\textsuperscript{78-80} In addition, in all the three biomarkers examined in this meta-analysis, individuals with Asian ethnicity have higher rates of polymorphism.\textsuperscript{81-83} The presence of high rates of the polymorphism can be an additional factor explaining the lower rates of post-stroke motor improvement seen in this population. This information can likely play an important role in prediction of prognosis after a stroke. Furthermore, it can also help make decisions as to whether and if so, the extent to which provision of rehabilitation interventions need to differ for this population.

Limitations

We only included studies involving adult participants published in English (since no one in the team was proficient in other languages). It might be possible that we missed studies published in other languages. None of the studies had an explicit sample size calculation. Information on baseline levels of depression and/or intake of anti-depression medication was
available in only two studies. Information on the presence of depression is essential, as the presence of genetic polymorphisms is an additional risk factor for post-stroke depression and can influence the extent of UL motor improvement.

**Conclusion**

Our review and meta-analyses results indicate that presence of genetic polymorphisms in BDNF and COMT negatively impact post-stroke motor improvement. This is especially true at the body-structure and function domain of the ICF. Our findings may contribute to the understanding of one of the underlying mechanisms to help explain some variability in post-stroke UL motor improvement. This is valuable information for the means of tailoring a plan of care, creating realistic goals, and providing relevant, individualized care to every patient. In addition, new questions have been identified including does the i) use of a fixed number of repetitions result in similar or better levels of UL motor improvement in individuals with genetic polymorphisms; ii) presence of COMT val<sup>158</sup>met continue to influence motor improvement at retention testing; iii) presence of genetic polymorphisms influence participation levels and iv) do individuals with genetic polymorphisms use altered movement patterns and if so, to what extent. Answers to these emergent questions can help better understand the influence of genetic polymorphisms on post-stroke upper limb motor improvement.

**Declarations**

- **Ethics approval and consent to participate:** Not applicable, as this manuscript is a systematic review. However, ethics approval was obtained for all the studies included.

<td>Robotic therapy spread over 2-3 weeks.</td>
<td>Therapy consisted of repeated grasp and release movements of the affected hand and wrist. Participants wore a Hand Wrist Assistive Rehabilitation Device and practiced tasks with real objects as well as virtual reality games (e.g., robotic therapy).</td>
</tr>
</tbody>
</table>

- UL FMA scores
- Values of fractional anisotropy (FA), axial diffusivity (AD) and radial diffusivity (RD) for CST.

Assessments conducted at baseline, T1 (1 month after baseline) and T3 (3 months after baseline). **UL FMA scores**

- Greater change in the Val/Val group at T2 (7 points) and T3 (17 points) compared to the Met group (4 and 12 points respectively).
- Moderate positive correlation with FA Values at T1 (r = 0.78) and T2 (r = 0.72) for the Val/Val group and at T3 (r = 0.59) for the Met group.
- Moderate positive correlation with AD scores at T1 (r = 0.78) and T2 (r = 0.72) for the Val/Val group.
- Moderate negative correlation with RD Values scores at T3 (r = -0.59) for the Met group.

- No difference in change in UL FMA scores between the Val/Val group at T2 (2.1 points) and the Met group (3.2 points) at the end of therapy.
- However, the Val/Val group had greater percentage signal change (p = 0.037) and activation volume (p = 0.03) in the ipsilesional primary sensorimotor cortex.  

Individuals with Val/Val genotype almost twice more likely to have better improvement than those with Met alleles.

Identification of studies via databases and registers

Identification

- Records identified from PubMed (n = 119) and Google Scholar: (n = 200)

Records removed before screening:
- Duplicate records removed (n = 192)

Screening

- Records screened (n = 187)

- Records excluded (n = 16)
  * Reasons for exclusion:
    - Studies including healthy participants (n = 3), other conditions (including TBI, Myasthenia Gravis, CoViD, Cardiovascular diseases, Schizophrenia, Diabetes, Cerebral palsy, Neuro-developmental Disorders; n = 13)

- Reports not retrieved (n = 85)
  - Reviews = 13,
  - No inclusion of rehabilitation/clinical outcomes: 72

- Reports excluded: 21
  - Global Rehabilitation outcomes such as BI, NIHSS and/or mRS: (n = 17)
  - Gait outcomes: (n = 4)

Included

- Studies included in the qualitative review (n = 10) and quantitative analyses (n = 6)
