Abstract

Objectives

We sought to compare two of the most promising plasma biomarkers for Alzheimer disease: pTau181 and pTau217.

Methods

pTau181 and pTau217 were quantified using SIMOA Quanterix and ALZpath assays in the well characterized prospective multicentre BALTAZAR cohort of mild cognitive impairment (MCI) participants.

Results

Among MCI participants, 55% were Aβ+ and 29% developed dementia due to AD. pTau181 and pTau217 were higher in the Aβ+ population with fold-change of 1.5 and 2.7 respectively. Concentration were also higher in MCI that converted to AD versus with hazard ratio of 1.38 (1.26-1.51) for pTau181 compared to 8.22 (5.45-12.39) for pTau217. The AUC for predicting Aβ+ was 0.783 (95%CI: 0.721-0.836; cut-point 2.75 pg/mL) for pTau181 and 0.914 (95%CI: 0.868-0.948; cut-point 0.44 pg/mL) for pTau217. The predictive power of pTau217 was not improved by adding age, sex, and APOEε4 status in a logistic model. The confounding factors of age, APOEε4 or renal dysfunction were associated with both pTau levels, but pTau217 clinical performance was only marginally modified by these comorbidities. Using a two cut-point approach, a 95% positive predictive value for Aβ+ corresponded to pTau217 > 0.8 ng/mL and a 95% negative predictive value at <0.23 ng/mL. At these two cut-points, the percentages of MCI conversion were 56.8% and 9.7% respectively, while the annual rates of decline in MMSE were -2.32 versus -0.65.

Conclusions

Plasma pTau217 and pTau181 both correlate with AD, but the fold-change in pTau217 make it better to diagnose cerebral amyloidosis, and predict cognitive decline and conversion to AD dementia.
**Introduction**

Alzheimer disease (AD) is a problem that needs close monitoring for better management in an aging society where it is more and more prevalent. AD likely follows a trajectory; amyloid build-up is thought to be the preclinical starting point in cognitively unimpaired people. These people start to have cognitive problems in this ‘prodromal’ stage. This mild cognitive impairment (MCI) is associated with gradual build-up of neuronal tau tangles and conversion to dementia due to AD. There is an urgent need for the use in clinical practice of biomarkers for these early stages to better manage the disease.

The protein at the heart of AD, Tau, exists in many post-translationally modified protein isotypes. Tau has many phosphorylation sites, many of which are in the proline-rich region, and some of these have been posited as useful biomarkers. Two of the moieties that have generated the most interest are threonines 181 and 217. Although pTau181 is a useful marker to predict amyloid status and conversion to dementia, many publications in the last three years are painting a picture whereby pTau217 is even more promising. For example, in 2020 cerebrospinal fluid (CSF) pTau217 was already found to outperform pTau181 to detect AD. A likely crucial factor in this superiority was that the fold-change in CSF was greater for phosphorylation position 217 than for 181.

The brain changes that occur in AD can currently be assessed in patients by two methods: either by PET or by CSF analysis. It is thus essential to find blood biomarkers that mirror these more invasive/expensive/lengthy tests as a pre-screen. As mentioned above, many studies have also found plasma pTau217 highly specific in distinguishing AD from normal, e.g. Indeed, plasma pTau217 is as good as any CSF markers or as PET screening to discriminate AD from other diseases. pTau217 can also distinguish AD from other forms of dementia like FTLD. Even more importantly from a clinical perspective, plasma pTau217 can distinguish different stages of the AD trajectory.

Several studies have demonstrated a link between pTau217 and cerebral amyloidosis (Aβ+). pTau217 has the power to detect Aβ+ MCI and Aβ+ can be detected with an AUC of 0.91. For example, Doré and colleagues found that preclinical subjects that are Aβ+ had twice the level of pTau217 rising to 3.5X in cognitive impairment. The Hansson group have shown that pTau217 correlates with clinical deterioration, cognitive decline and brain atrophy and can detect the difference between CU Aβ+ and Aβ- making it a surrogate marker for preclinical and prodromal AD. In fact, plasma pTau217 is a predictor of poor cognitive
and conversion to AD. Plasma pTau217 builds up for two decades before the onset of symptoms and plasma pTau217 and 231 build-up earlier than Aβ PET can detect changes.

Three different tests were compared by Janeldzide et al: ADx, Wahington U and Lilly with similar results. The Janssen test also gave similar results, although there are some doubts about its sensitivity. Similarly, the Lilly and MSD tests were found to be insufficiently sensitive to pick up pTau217 all the time. More recently the UGot test, gave good results.

Not all the pTau217 assays used in these studies are available off-the-shelf to all investigators. Indeed, the ALZpath plasma pTau217 assay, which we evaluate below, is in fact the first scalable commercially available test. An article preprint has already suggested it is accurate in detecting AD pathology. In our results presented below this assay is comparable to other pTau217 assays in identifying cerebral amyloidosis, cognitive decline and conversion to AD dementia. Moreover, our study integrates the evaluation of comorbidities since the BALTAZAR cohort includes biomarkers designed to monitor metabolism, nutrition, diabetes and cardiovascular risk. Importantly, unlike for pTau181 the impact of comorbidities on performance seems to be limited probably in relation with the high fold change observed between normal and pathological groups. We therefore propose useful thresholds to confirm or rule out the presence of cerebral amyloidosis, information that can be used to stratify patients to select those who will benefit from the last line of anti-amyloid treatment.

Materials and Methods

Study population

This study included MCI participants of the BALTAZAR multicenter prospective cohort (ClinicalTrials.gov Identifier #NCT01315639). All participants had clinical, neuropsychological, brain MRI and biological assessments (see below). Right and left hippocampal volumes were obtained for each participant using virtual segmentation of the hippocampus. APOE was genotyped in a single centralized laboratory. MCI subjects were selected according to the Petersen criteria. Participants were assessed for conversion to dementia every six months for three years. The progression from MCI to dementia was defined by evaluation of the following parameters: (i) decline in cognitive function measured by mini-mental state examination (MMSE), (ii) disability in activities of daily living (ADL)
and (iii) clinical dementia rating sum of boxes. Conversions from MCI to AD dementia were reviewed by an adjudication committee. Participants were categorized, as amyloid-positive (Aβ+) or negative (Aβ-), based on their cerebrospinal fluid Aβ42/Aβ40 (ratio below 10% as measured with Euroimmun ELISA assays). Blood samples were taken at the first visit and, to minimize pre-analytical and analytical problems, identical plasma collection tubes were used across centers. Plasma aliquots were stored at -80°C until testing.

**Plasma pTau Measurement**

Plasma pTau was determined, using the Quanterix method that is based on ultrasensitive Simoa technology \(^{28}\), on an HD-X analytical platform. Plasma pTau181 was measured with a commercial Advantage V1 kit (#104111). This assay has a low limit of detection at 0.019 pg/mL and a low limit of quantification at 0.085 pg/mL. Quality controls, with low (QC 1 with mean concentration of 3.82 pg/mL) or high (QC 2 - 52.4 pg/mL) assigned p Tau181 concentrations, are provided in the kits. Inter-assay coefficients of variation for QC 1 and QC 2 were 7% and 5%, respectively. Plasma pTau217 was detected using a novel immunoassay developed by ALZpath, utilizing a proprietary monoclonal pTau217 specific antibody. For this assay, the low limit of detection is 0.0052 pg/mL and the limit of quantification was 0.06 pg/mL. Intra- and inter-run precision were 11.4% and 14.6%, respectively.

**Biological Biomarker Measurements**

Blood samples, taken at baseline, were used for determination of routine parameters in ISO15189-certified laboratories: fasting glycemia, triglycerides, cholesterol (total, high-density lipoproteins (HDL), low-density lipoproteins (LDL)), creatinine, prealbumin, albumin, total protein, C-reactive protein (CRP), hemoglobin, vitamin B12, thyroid stimulating hormone (TSH), folate, and red-cell folate \(^{26}\). Estimated glomerular filtration rate (eGFR) based on creatinine, age, and sex was calculated using the CKD Epidemiology Collaboration (CKD-EPI) equation, revised in 2021 without inclusion of race \(^{29}\). High molecular weight (HMW) adiponectin was measured on stored samples using the LUMIPULSE G platform.

**Statistical Analyses**

General characteristics were analyzed in the MCI sample overall and in converter and non-converter MCI subsets. Categorical variables were analyzed as percentage and counts (% (N)), continuous variables as mean and standard deviation (M (SD)) or median [25-75 percentile IQR] and comparisons were made by \(\chi^2\) test, t-test, Mann-Whitney U test or...
analysis of variance (ANOVA, Kruskal-Wallis test). Cox proportional hazards regression models for conversion, with time to dementia as a dependent variable, were computed, with adjustment for age at blood draw, sex, and APOE ε4 allele carrier status. We additionally plotted Kaplan-Meier curves for the different pTau tertiles and differences between tertiles were calculated by Log rank test. For all analyses, a two-sided α-level of 0.05 was used for significance testing. Receiving Operator Characteristic (ROC) curves, using conversion as a dependent variable, were also used. The corresponding areas under the curve (AUCs) were compared using the Delong method 30. For each comparison, the size of the different groups is indicated in the tables. Missing data have not been imputed. All analyses were performed using MedCalc (20·118) and R (R Core Team (2019)) software.

**Results**

**Baseline MCI participant characteristics**

A subset of 473 MCI patients from the BALTAZAR cohort 26 was studied (Table 1). Mean age at baseline was 77.7 [SD 5.5] years. 28.5% of the subjects (135/473) converted to AD dementia during the 3-year period 31. Subjects who converted to AD dementia (MCI converters) did not differ from non-converters regarding their age, sex distribution, body mass index (BMI), or educational levels (Table 1). The average MMSE score was 26.4 [SD 2.5] and 39.1% (184/470) of the MCI participants were APOE ε4 carriers. MCI converters had lower MMSE at baseline and a much higher MMSE decline per year, at -3.45 [SD 4.26] on average vs. -0.42 [SD 1.89] for the non-converter population. Hippocampal volume (R+L) (cm³) was also lower in converters than in non-converters. All these differences remained significant after adjustment for age, sex, APOE ε4 and the educational status. pTau217 levels were always lower than pTau181 levels; respective mean plasma levels in the MCI population were 0.49 [SD 0.34] vs. 3.18 [SD 1.49] pg/mL. The two sets of values were however correlated (Pearson correlation coefficient 0.73 [CI 95% 0.68-0.77], significance level p<0.0001).

**Plasma pTau217 and pTau181 in Aβ- and Aβ+ Participants**

In the subgroup of MCI with available CSF amyloid measurements, participants could be stratified in Aβ- and Aβ+ according to their CSF Aβ42/Ab40 ratio. Both plasma pTau217 and pTau181 levels were higher in Aβ+MCI than in Aβ- (0.75 [SD 0.34] vs. 0.28 [SD 0.19]
pg/mL for pTau217 and 3.87 [SD 1.38] vs. 2.6 [SD 1.42] pg/mL for pTau181) (Figure 1AB, Table 1). However, fold-change was much higher for pTau217 than for pTau181 (2.7 vs. 1.5). The AUC for Aβ+ detection was significantly higher for pTau217 (0.914 (95% CI: 0.868-0.948) than for pTau181 (0.783 (95% CI: 0.721-0.836) (Figure 1, Supp Table 1). Optimal cut-points were determined by Youden index at 0.44 pg/mL and 2.75 pg/mL for pTau217 and pTau181, respectively. The AUCs increased non-significantly in a logistic regression model with age, sex, and APOE ε4 status (Figure 1CD, Table 2). Regarding the comorbidity blood biomarkers, folate and CRP concentrations were slightly lower in the Aβ+ population (Supp Table 1) but if we use a Bonferroni adjustment linked to the multiple comparison of comorbidities factors, it does not reach the significance (p>0.001).

**Plasma pTau217 and pTau181 predict cognitive decline and conversion to AD dementia**

For MCI participants that converted to AD versus those that did not, the respective values were 0.69 [SD 0.37] vs. 0.41 [SD 0.29] pg/mL for pTau217 and 3.81 [SD 1.53] vs. 2.93 [SD 1.39] pg/mL for pTau181 (Table 1). In a Cox proportional hazard model, conversion to AD dementia, during our three-year follow-up after adjustment for age, sex, and APOE ε4 status, showed a significant risk for age, MMSE, APOE ε4, hippocampal volume, pTau181 and pTau217 (Table 3). pTau217 had a higher hazard ratio at 8.30 (5.46-12.61), compared to 1.38 (1.26-1.52) for pTau181. Importantly, none of the comorbidity biomarkers were independently associated with an increased risk of conversion (Supp Table 2). The relative risks of conversion to AD dementia, as predicted by high plasma pTau217 and pTau181, is illustrated by Kaplan-Meier curves of pTau tertiles (Figure 2AB). The hazard ratios (HRs) between the 1st and the 3rd tertile were 7.37 [95%CI: 4.86-11.16] and 3.83 [95%CI: 2.54 -5.79] for plasma pTau217 and pTau181, respectively. We also tracked changes in MMSE over 18 months (Figure 2CD), and found the steepest decline for the p217-high, third, tertile. The three p217 tertiles each predicted distinct cognitive decline trajectories. The differences were less significant for pTau181 with a smaller different between low and medium and no further effect in the third pTau181 tertile.

**Association of plasma pTau217 and pTau181 levels with different biomarkers and cohort characteristics**

The relationships, between plasma pTau concentrations and demographic or biological factors, collected at baseline in the BALTAZAR cohort, were studied using a linear regression approach. Plasma pTau217 and pTau181 were associated with BMI and APOE
status (Figure 3A). The presence of at least one APOE ε4 allele was associated with significantly higher pTau values (t-test between APOE ε4 negative and positive population: p<0.0001). Levels of both pTau isoforms were also strongly related to renal function parameters: creatinine and eGFR (panel B). CRP for both isoforms and total protein for pTau181 were the only other biomarkers clearly associated with pTau levels. To further assess the impact of renal function on pTau performance, participants were stratified using eGFR values between normal, slightly reduced or impaired renal function (Figure 3CD). Impaired renal function was associated with increased pTau values in both the Aβ- and Aβ+ MCI populations. Renal function had a significant impact on the performance of pTau181, with the optimal cut-point not separating the two populations well. On the other hand, renal parameters had little effect on plasma pTau217 performance, likely because this biomarker showed a much higher fold change between the Aβ- and Aβ+ populations than pTau181.

**Definition of pTau217 cut-point to detect cerebral amyloidosis**

At the optimal threshold of 0.44 ng/mL, deduced from the ROC analysis, the positive predictive value (PPV) for Aβ+ detection was 88.5% and the negative predictive value (NPV) was 84.0% (Table 2). To achieve a PPV of 95%, plasma pTau217 had to be above 0.8 ng/mL, while to achieve an NPV of over 95%, pTau217 must be below 0.23 ng/mL. At these two cut-points, the percentage of MCI converting in three years into AD dementia was 56.8% and 9.7% respectively, while the annual rate of decline in MMSE was -2.32 and -0.65 (Table 4).

**Discussion**

This study examines the performance of plasma pTau181 and pTau217 in monitoring Alzheimer's disease (AD) parameters in the BALTAZAR cohort with data on 473 participants with mild cognitive impairment (MCI) over a three-year period, with regular assessments and biological fluid tests. Our main finding is that plasma pTau217 can accurately assess the presence of cerebral amyloidosis, with a confidence level above 95%, and that this biomarker predicts conversion of MCI to Alzheimer's-type dementia and cognitive decline. Plasma pTau217 performs significantly better than plasma pTau181 and overall, our results confirm previous observations in other large cohorts.

However, commercially available assays of proven accuracy are required before pTau217 can move to the clinic. Most published studies on pTau217 had one drawback: the tests were not commercially available to standard clinical laboratories. These studies used in-house or proprietary assays that were not commercially available. With interest in pTau217, this
picture is set to change rapidly and, to date, no published work uses a commercially available assay. Our data will therefore be essential for the general deployment of clinical tests, which must comply with ISO15189 standards and be based on previously validated studies.

As well as clinical reproducibility, interpreting plasma pTau217 levels will require knowledge of the medical context to be useful. An important factor for real-life use of assays in large populations is knowledge of the confounding factors that induce bias in the measurements. Indeed, it has been established that certain comorbidities, and in particular impaired renal function, can significantly modify the predictive value of plasma biomarkers. Other parameters such as age or BMI can also confound the value of AD prognostic biomarkers. For pTau181, we previously found impaired renal function likely undermines diagnostic performance \(^\text{32}\). In the same cohort, we now study pTau217 and we observed that renal function and other potential confounding factors have a minimal effect on its performance. This is likely due to the high fold-change observed between normal and pathological situations. These results pave the way for wider, independent use of this marker. Note that none of the other factors we tested, such as age, sex, BMI, level of education or ApoE \(\epsilon 4\) genotype, either separately or together, significantly improve the independent predictive value of plasma pTau207 by more than an AUC of 0.02.

We are therefore in a situation where this marker alone is capable of providing major information for patient management, not only with regard to the presence of cerebral amyloidosis, which is important for anti-amyloid treatment selection and for diagnostic strategy \(^\text{33}\), but also, for prognosis. Indeed high plasma pTau217 levels are associated with a high risk of conversion to AD dementia within three years. We can also see that cognitive evolution can be stratified with this marker, which is important information for the clinician.

For clinical use, it is also necessary to define one or more pathological cut-points, and recent papers have proposed for pTau217 different approaches depending on the medical need \(^\text{3} \ 25 \ 34 \ 35\). A universally applicable plasma pTau217 cutting would be useful for the management of patients presenting cognitive disorders. General practitioners would then greatly appreciate a threshold ‘diagnosing’ cerebral amyloidosis with a 95% confidence level. In our cohort, the cut-point of > 0.44 pg/mL is a useful combination of sensitivity and specificity (>85%) and the cut-point of > 0.8 pg/mL gives a 95% positive predictive value for cerebral amyloidosis. Conversely, it is also very useful for patient management to be able to exclude the presence of cerebral amyloidosis with a high level of confidence (>95%). In our case, this low cut-
point value is < 0.23 pg/mL. The intermediate zone of our study, or grey zone, between these two thresholds, represents 55% of the population. This percentage seems higher than in previous studies\(^3\). The explanation certainly lies in our study population, which includes only MCI participants, and in the methods for detecting Aβ+ and pTau217.

The present study has some limitations. To increase the likelihood of conversion to AD we excluded participants with Lewy Body, Parkinson, frontotemporal or vascular MCI disorders. Therefore 77% of subjects had amnestic MCI and 28% of participants developed AD dementia. Amyloid status was available in only a part of the population, since the BALTAZAR study focused on conversion, and it was defined using CSF biomarkers rather than with PET amyloid.

The main strengths of the study lie in the large sample size of MCI participants that are well described, the controlled pre-analytical conditions, the use of a commercially available plasma pTau217 assays and the consideration of clinical chemistry analyte measurement realized at baseline.

**Conclusion**

These data place us at the dawn of a major change in the management of AD patients. This is linked to the clinical use of the plasma marker pTau217, whose performance using commercially available assays is exceptional both in terms of identifying cerebral amyloidosis and, as we have shown in this article, in predicting progression to Alzheimer's dementia and accelerated cognitive decline. This information is essential for optimal patient management, including diagnostic strategy, prevention and access to disease modifying therapy.

Figure legends

**Figure 1** Distribution and ROC curves of plasma pTau217 and pTau181 in MCI according to amyloid status. Values of pTau217 (A) and pTau181 (B) in pg/mL are represented in the Aβ- and Aβ+ populations. (C) ROC curves. Both biomarkers were significantly different between these two populations and a logistic regression model combining pTau values with age, sex, and APOE4 status gave slightly higher AUCs. (D) AUCs with 95% CIs. A DeLong test was used to compare the different AUCs.

**Figure 2** – Conversion to AD dementia and MMSE evolution according to pTau181 or pTau217 tertiles Plasma pTau217 and pTau181 measurements were separated into tertiles and conversion to AD dementia determined at six-month intervals over three years (Panels AB). A very significant overall difference was observed for both pTau217 and pTau181 (Logrank test (overall difference) 76.1 and 46.7 respectively, both P < 0.0001). However, hazard ratio (HR) between 1st vs 3rd tertile was 7.37 (4.86 to 11.16) compared to just 3.83 (2.54 to 5.79 for plasma pTau217 and pTau181, respectively. The average slopes of MMSE decline per year in pTau terciles are plotted in panels CD. Grey shadows show the confidence interval. Lower lines show increasing tertile: first tertiles are green, second tertiles, blue, and third tertiles are orange.

**Figure 3** – Association of plasma pTau217 and pTau181 levels with different biomarkers and cohort characteristics Forest plots of associations between demographic (panel A) and comorbidity (panel B) biomarkers and plasma pTau217(red) or pTau181(blue), using linear regression of z-scores. Means and 95% confidence intervals (CIs) are provided. The concentrations of plasma pTau217 (panel C) or pTau181(panel D), in Aβ- (orange) and Aβ+ (blue) participants, are represented in participants stratified by their estimated glomerular filtration rate (eGFR), (eGFR<60: impaired renal function; 60-90 mildly reduced renal function, >90 normal renal function). The value corresponding to the optimal cut-points for Aβ+ detection (Youden index) in all the population is represented by a dotted line. Note that the line separates the Aβ- and Aβ+ population for pTau217 only. Abbreviations: APOE, apolipoprotein E; BMI, body mass index; eGFR, estimated glomerular filtration rate; MMSE, Mini–Mental State Examination.

</table>

Values in the number (n) of MCI participants for which different data types were available and comparison between non-converter and converters, with t-student or χ² and linear regression adjusted for age, sex, and the presence of the APOE ε4 allele; numbers were used to describe categorical variables. mean ± standard deviation for continuous variables.

Abbreviations: MCI: mild cognitive impairment; APOE: apolipoprotein E; BMI, body mass index; MMSE, Mini–Mental State Examination; sd, standard deviation.
