NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.
**Objective:** Aortic clamping time during cardiopulmonary bypass (CPB) has been associated with inflammatory processes such as systemic inflammatory response syndrome. In this study, we evaluated the association of CPB and aortic cross-clamping (ACC) times with systemic inflammatory response index (SIRI) and systemic immune inflammation index (SIII) in isolated coronary artery bypass surgery (CABG).

**Methods:** 96 patients who underwent isolated CABG at a single center between 2021 and 2023 were retrospectively analyzed. Patients were divided into below median aortic clamp time (group I; n=56) and above median aortic clamp time (group II; n=42) according to median aortic clamp time (66.2 minutes). Demographic data, preoperative and postoperative laboratory parameters were recorded. SIRI and SIII values were calculated.

**Results:** Baseline demographic data were similar between the groups. The duration of CPB and aortic clamping was significantly longer in group II (p<0.001). SIII and SIRI values were significantly increased in both groups in the postoperative period. However, there was no correlation between increased CPB and ACC durations and SIII and SIRI. However, no significant difference was observed in postoperative SIII and SIRI values between the groups. A weak correlation was found between SIII index and postoperative albumin levels.

**Conclusions:** There is no significant relationship between aortic clamping time and inflammatory indices in patients undergoing isolated CABG surgery. Increasing the duration of surgery does not affect the change in SIRI and SIII values.

**Keywords:** Coronary artery bypass; Cardiopulmonary bypass; Systemic immune inflammation index; Systemic inflammation response index.
1. Introduction

During cardiopulmonary bypass (CPB), the patient receives constant blood flow through a mechanical pump (1). In CPB, a cross-clamp is placed over the aorta to provide an immobilized and bloodless operating field (2). Systemic inflammatory response syndrome (SIRS) is an inflammatory process that can be triggered by cardiac surgery and CPB. SIRS is associated with the release of several proinflammatory mediators after open heart surgery procedures that may affect postoperative outcomes (3).

The marked increase in SIRS after coronary artery bypass grafting (CABG) may be related to the duration of perioperative CPB and aortic cross clamping (ACC). Many studies have shown that the duration of CPB and ACC during cardiac surgery are predictors of mortality and morbidity. However, there is no consensus on the safe time limit. In this regard, researchers have reported different results for the safe use of CPB and ACC (4,5).

The concepts of systemic inflammatory response index (SIRI) and systemic immune inflammation index (SIII) have been defined as new inflammatory markers (6,7). These indices include the main components of inflammatory markers such as neutrophils, monocytes, lymphocytes and platelets and have been presented as possible mortality prognostic factors in different cardiovascular diseases (8,9).

In this study, we tried to determine the relationship between aortic clamping time and inflammatory indexes in isolated coronary artery bypass surgery.

2. Methods

2.1 Study Design and Patients

The population of this retrospective study consisted of 96 patients undergoing first-time isolated CABG at a single center between June 2021 and September 2023. Patients over 18 years of age who underwent elective isolated on-pump coronary artery bypass surgery were included. Reoperations, patients with additional surgical procedures, patients with known
cerebrovascular disease, bleeding pathology and patients with incomplete medical data were excluded. The study groups were divided into those with a median aortic clamping time of the total population below (Group I) and above (Group II) 66.2 minutes. The study was approved by XXX University Non-Interventional Research Ethics Committee with the ethics committee decision dated 16.01.2024 and numbered 2024-1.

2.2 Data collection and calculation of inflammatory indexes

Demographic data, preoperative and postoperative hematologic and biochemical analyses, and clinical data including postoperative processes were obtained by examining the computerized patient record system. SIRI and SIII indexes related with systemic inflammation were calculated as follows (10). SIII; peripheral platelet count x neutrophil count / lymphocyte count. SIRI; neutrophil count x monocyte count / lymphocyte count

2.3 Operative technique

All patients underwent standard median sternotomy under general anesthesia. After appropriate anticoagulation with 400 IU/kg heparin, cardiopulmonary bypass (CPB) was initiated by cannulation of the ascending aorta and right atrium. All patients were monitored with moderate hypothermia (28 - 32 °C) and myocardial protection was achieved with antegrade-retrograde combined blood cardioplegia. Mean arterial pressure was maintained between 60 and 80 mmHg during CPB. After the procedure was completed, CPB was terminated after the body temperature of the patients was raised to 37 °C. Decanulation was performed after neutralization with protamine.

2.4 Statistical analysis

Statistical evaluation was performed with IBM SPSS 25.0 (SPSS Inc., Chicago, IL, USA) package program. While evaluating the study data, quantitative variables were represented by mean, standard deviation, median, min and max values, and qualitative variables were represented by descriptive statistical methods such as frequency and percentage. Shapiro
Wilks test and Box Plot graphs were used to evaluate the conformity of the data to normal distribution. Student’s t-test was used for quantitative two-group evaluations showing normal distribution, and Mann Whitney-U test was used for those not showing normal distribution. Between two follow-ups, Paired Samples test was used for those with normal distribution and Wilcoxon test was used for those without normal distribution. Chi-Square test and Fisher Exact Test were used to compare qualitative data. Pearson correlation analysis was used to evaluate the relationships between variables. The results were evaluated at 95% confidence interval and significance was evaluated at p<0.05 level.

3. Results

A total of 96 patients who underwent isolated CABG were included in the study. The mean ages of the patients included in the study were 63.6±8.8 years for group I and 66±8.9 years for group II (p>0.05). 64.8% of patients in group I and 73.8% of patients in group II were male. The study groups were divided into those with a median aortic clamping time of the total population below (Group I) and above (Group II) 66.2 minutes. The mean aortic clamping times were 51.7±10.7 minutes for group I and 89.9±13.0 minutes for group II (p<0.05) (Table 1).

The changes in the parameters within and between the groups at preoperative and postoperative 24th hour periods are shown in Table 2. Significant differences were found between group I and group II in SIII, SIRI, CRP and albumin values at preoperative and postoperative 24 hours. In the comparison between the groups, preoperative and postoperative SIII, SIRI and albumin values were similar. Although there was a statistical difference in preoperative CRP levels between the groups, no statistical difference was found between the CRP values in the postoperative 24th hour measurements (Table 2). The graphical changes of SIII and SIRI parameters of group I and group II are shown in figures I and II.
When the correlation of SIRI and SIII values with CPB and ACC duration, postoperative albumin and CRP values were analyzed, it was found that only postoperative SIII value had a weak correlation with postoperative albumin level (r=0.240; p=0.019) (Table 3). No statistically significant correlation was found for other postoperative variables.

4. Discussion

To our knowledge, this is the first study to present the relationship and variation of different inflammatory indices with aortic cross-clamping time in on-pump coronary artery bypass surgery. In this retrospective study, we evaluated the relationship between aortic clamp duration and inflammatory indices in 96 patients undergoing isolated CABG surgery. Different studies have shown that some complications develop and the risk of death increases in patients exposed to prolonged aortic cross-clamping (11,12,13).

The systemic immune inflammatory index (SIII) is an inflammatory index that includes three differently shaped elements involved in the immune response, including neutrophils, lymphocytes and platelets. This index has been reported to be a prognostic marker used to determine long-term prognosis in coronary revascularization (14). Researchers have also described this index as an important marker reflecting the inflammatory status in various clinical pictures including appendicitis, coronary artery disease and neoplasms (15,16,17).

Systemic inflammatory response describes the pathophysiologic response of the immune system to events such as infection, trauma, burns and various other injuries (18). Many factors associated with the contact of blood with extracorporeal artificial circuits in cardiac surgery contribute to SIRS formation (19). The systemic inflammatory response index (SIRI) is defined as an inflammatory index describing immunologic defenses involving neutrophils, monocytes and lymphocytes (20).

Although CPB is considered a safe method to facilitate cardiac surgery, prolonged CPB is associated with complications (21). Exposure of blood to abnormal shear stress and contact...
with the artificial surface of the bypass circuit leads to pro-inflammatory activation of the
coagulation and complement systems, endothelial cell death and platelet activation (22,23,24).
In addition, prolonged aortic cross-clamping time is known to be associated with decreased
early survival after cardiac surgery (25). It is not known how the inflammatory indexes SIII
and SIRI, which have emerged as a prognostic factor for cardiovascular diseases, change
depending on the duration of CPB and aortic cross-clamping. In our study, we tried to
determine the effect of different aortic cross-clamping times on these indexes in patients
undergoing isolated on-pump CABG.
We divided the included patients into two groups according to the median aortic cross-clamp
time (66.2 min) of patients undergoing isolated CABG. The aortic cross-clamp time was
51.7±10.7 and 89.9±13.0 min in group I and group II, respectively. Baseline demographic
characteristics of the patients were similar. Mean CPB duration was 103.8±20 and 134.4±21.3
min in group I and group II, respectively. Preoperative SIII and SIRI values were similar in
both groups. In the postoperative period, there was an increase in these indices within the
groups. We think that this is related to the increase in the inflammatory response to CPB.
However, postoperative SIII and SIRI indices were similar between the groups. This suggests
that the relatively long aortic clamping time did not affect the inflammatory indices. Robic M
et al. reported that a longer duration of CPB was associated with increased blood neutrophil
count (26). In our study, it was determined that the SIII value including the neutrophil
parameter was not related with duration.
C-Reactive Protein (CRP) increases significantly in response to inflammation. CRP levels
increase significantly after cardiac surgery with CPB (27). In our study, although
postoperative CRP values increased statistically significantly in both groups compared to
preoperative values, postoperative measurements were similar between the groups. In cardiac
surgery with CPB, serum albumin levels decrease with the effect of hemodilution (28). At the
same time, high inflammation parameters have been independently associated with hypoalbuminemia (29). In our study, a significant decrease in postoperative serum albumin levels was observed in both groups and postoperative serum albumin levels were similar between the groups.

There was no correlation between postoperative SIII and SIRI indices and CPB duration, aortic clamping duration and CRP levels. However, a weak statistically significant correlation was found between postoperative SIII index and postoperative albumin levels ($r=0.252; p=0.018$).

Our study is the first to evaluate the relationship between inflammatory indices and operative times in patients undergoing isolated CABG surgery. However, there are some limitations. First of all, our study has a non-randomized design because it is retrospective. This creates the possibility of limiting the population included. In addition, the fact that it is a single-center study also limits the sample size. We believe that the relationship between CPB and inflammatory indices should be investigated in detail with a larger sample group.
