Abstract

Gastric milk protein (MP) coagulation has been extensively studied using in vitro and animal models. Yet, verifying these results in humans remains essential. Recently, we demonstrated that $^1$H Magnetization Transfer (MT) MRI can be used for the assessment of gastric MP coagulation in vitro. In the present follow-up study, we assessed the feasibility of using MT MRI for monitoring MP coagulation in vivo in humans. Twelve healthy adults underwent MRI scans before and after ingesting 300 g of low- or high-pasteurized skim milk (LPSM or HPSM, respectively). We assessed coagulation and gastric emptying (GE) dynamics by deriving the MT ratio ($MTR$), the total gastric content (TGC), semi-solid, and liquid volumes. The $MTR$ values increased during digestion for both milk products, indicating a decrease in protein molecular mobility and a concomitant increase in the degree of coagulation. Prolonged heating of milk did not affect the $MTR$ ($p = 0.15$), but resulted in higher TGC volumes (MD 40.3 mL, 95% CI [25.5-55.1], $p = 0.044$) with a trend towards greater semi-solid ($p = 0.056$) or liquid ($p = 0.065$) volumes. These findings suggest that prolonged heating of milk leads to slower GE. We thus showed that by combining MT with conventional anatomical MRI both MP coagulation and GE dynamics, and thereby the impact of heating on gastric milk digestion, can be assessed in vivo in humans. Our work underpins the feasibility of using MRI as a non-invasive imaging tool for studying the effect of food processing and composition on gastric digestion.
1. Introduction

There is an increasing socio-economical demand in linking food with health. To aid the development of innovative food products and processing methods for optimal health benefits, one of the necessary requirements is to understand the behavior of foods in our digestive system (Bornhorst & Paul, 2014). To this purpose, various static and (semi)-dynamic in vitro digestion models (Dupont & Mackie, 2015) have been developed, which simulate digestion in the human gastro-intestinal (GI) tract. Such models have found widespread use because they are simple to use, well controlled and do not pose ethical concerns. However, even sophisticated dynamic in vitro models do not fully capture the complexity of in vivo digestion, which includes neural and hormonal regulation as well as feedback controls. Therefore, in vivo data from humans is needed to gain a better understanding of food digestion, and to verify and inform in vitro digestion models. This requires the development of non-invasive methods that can be used to study food digestion both in vitro and in vivo in humans.

We have previously demonstrated that Magnetization Transfer (MT) $^1$H MRI is a powerful imaging approach for assessing structural changes that occur during static (Mayar et al., 2022, 2023) and semi-dynamic (Mayar et al., 2024) in vitro gastric digestion using cow’s milk, a widely consumed source of high-quality proteins, as a test case.

Cow’s milk contains approximately 3.5 w/v% protein, with caseins and whey proteins (WPs) constituting 80% and 20%, respectively (Bhat et al., 2016). Gastric digestion of cow’s milk involves acid- and pepsin-induced aggregation of casein micelles, which results in the formation of a semi-solid coagulum (Huppertz & Chia, 2021). The coagulation process results in reduced macromolecular mobility as liquid milk undergoes a transition into a semi-solid mass. In our prior in vitro work we demonstrated that this transition can be monitored using the $^1$H MT ratio (MTR) as an MRI marker of the coagulum consistency, and that differences in the coagulation behavior resulting from heat treatment can be assessed (Mayar et al., 2024).

Knowledge of the effect of heat treatment on gastric milk protein (MP) digestion is crucial because it can potentially be used to tune the gastric coagulation properties and the kinetics of the subsequent breakdown and absorption in the intestines. Therefore, gastric MP coagulation has been studied extensively with in vitro models (Li et al., 2022a; Mulet-Cabero et al., 2019; Ye et al., 2016a) and in vivo in animals (Ahlbom et al., 2023; Ye, Liu, et al., 2019). These studies have
shown that heat treatment results in a looser and softer coagulum consistency under gastric conditions, due to aggregation of WPs on the surface of casein micelles, resulting in reduced casein-casein interactions (Kethireddipalli & Hill, 2015). Moreover, a study in humans reported a higher dietary nitrogen (N) transfer into serum amino acids (AAs) and proteins for UHT compared to pasteurized milk (Lacroix et al., 2008). The authors suggested that this may have been caused by the looser and softer coagulum structure and faster gastric emptying (GE) of the UHT milk. However, recently, Milan et al. (2024) showed that GE measured by MRI was slower for UHT compared to pasteurized milk. Nevertheless, gastric coagulum formation and degradation were not directly considered in their study, and to date there are no in vivo human studies that have assessed the effect of heat treatment on intragastric MP coagulation. As demonstrated by our in vitro results, $^1$H MT MRI holds great potential for bridging this research gap (Mayar et al., 2022, 2023). However, studying gastric digestion is more challenging in vivo than in vitro, due to motion caused by breathing and gastric motility, as well as to large biological variation. Therefore, the first aim of this study was to assess the performance of $^1$H MT MRI for assessing gastric MP coagulation in humans using low- and high-pasteurized skim milk (LPSM and HPSM, respectively) as test products. Since the consistency of the coagulum may also affect GE, the secondary objective was to compare GE dynamics of LPSM and HPSM in terms of changes in total, semi-solid and liquid gastric content volume using $T_2$-weighted anatomical MRI images.
2. Materials and methods

2.1. Study design

The study was a single-blind randomized crossover trial in which healthy, normal-weight adults underwent gastric MRI scans at baseline and after consumption of two differently heated skim milk products. The primary outcome was the $^1$H MTR of the gastric content over time. Secondary outcomes were the total gastric content (TGC), the semi-solid and liquid volume fractions over time. Other outcomes were subjective ratings of appetite (hunger, fullness, thirst, desire to eat) and well-being (nausea and bloating). The study procedures were approved by an accredited Medical Ethical Committee (METC Oost-Nederland) and were in accordance with the Helsinki declaration of 1975 as revised in 2013. The trial was registered with clinicaltrials.gov under number NCT05854407. All participants provided written informed consent.

2.2. Participants

The study was conducted between June 2023 and September 2023 with 12 healthy (self-reported) adults ($n = 6$ males and $n = 6$ females, age $24 \pm 4$ years, body mass index (BMI) $22\pm2$ kg/m$^2$; Fig. S1 in the Supplementary Information (SI)). The sample size estimation can be found in the SI. Participants were recruited in the Ede and Wageningen area in The Netherlands via digital advertisements (email and Wageningen University website). The inclusion criteria were: age between 18 and 45 years; BMI between 18.5 and 25 kg/m$^2$; self-reported good general health. The main exclusion criteria were: lactose and milk protein intolerance or allergy; use of medication that may alter the normal functioning of the digestive tract; having a gastric disorder or regular gastric complaints ($\geq 1$ per week) and having a contra-indication for MRI including, but not limited to, pacemakers and defibrillators, ferromagnetic implants, or claustrophobia. Potential participants were informed about the details of the study via an online information meeting, followed by a screening session which involved tasting of the milk products, getting accustomed to undergoing MRI scans in a dummy MRI scanner, practicing drinking milk in a supine position and practicing the
breath holds required for the MRI scans. Volunteers that were still interested in participation were asked to sign the informed consent form and fill in the screening questionnaire.

2.3. Milk products

Commercial pasteurized skim milk (typically heated at 72 °C for 15 s) was purchased from a grocery store, and is referred to as Low Pasteurized Skim Milk (LPSM). High Pasteurized Skim Milk (HPSM) was prepared from LPSM by heating the latter in a water bath for 30 min after reaching a temperature of 80 °C. The WP denaturation level in the milk products was measured using SDS-PAGE (data not shown), and was 3% and 90% for LPSM and HPSM, respectively. The milk products were purchased or prepared within one week prior to the test session and stored at 4 °C. The milk was kept at room temperature for 30 min before the start of the test session. LPSM from the same brand was used throughout the study.

2.4. Study procedures

The participants visited the Hospital Gelderse Vallei in Ede, the Netherlands, twice in the morning between 7.30 and 9.30 am, in fasted state. There was a minimum of 1 and a maximum of 4 weeks between the two visits. Eating and drinking was allowed until 8:00 pm the night before, and drinking water was allowed up to 1 hour before the start of the test session. A schematic overview of the study session is shown in Fig. 1. Upon arrival, participants completed an MRI screening form. After that, a baseline abdominal MRI scan was conducted and the participants provided baseline verbal ratings of their appetite and well-being. Subsequently, participants drank 300 g (291 mL) of either LPSM or HPSM through a tube (similar to drinking from a straw), while lying in a supine position on the scanner bed. The mean ingestion time, with its standard deviation (SD), was 1.2 ± 1.1 min. MRI scans of the abdomen were performed at t = 5 min and subsequently at intervals of 15 mins up until 95 min after the start of ingestion. The participants were asked to verbally rate their appetite and well-being, on a scale between 0 and 100, after the MRI scanning at each digestion time. They remained in a supine position for the full duration of the MRI scanning. After this, they exited the scanner and were offered a takeaway breakfast.
Figure 1. Schematic overview of a test day consisting of MRI baseline measurements, drinking 300 g (291 mL) of milk in a supine position through a tube (similar to drinking from a straw), followed by MRI measurements of subjective ratings of appetite and well-being after 5 min from milk ingestion, repeated every 15 min up to 95 min.

2.5. MRI scans

Participants were scanned using a 3T MRI scanner with the dStream torso coil (Philips Ingenia Elition X, Philips Medical Systems, the Netherlands). All scans were performed during breath-holds. Participants were asked to hold their breath on expiration to minimize motion. The breath hold duration was at most 21 s. At each timepoint, Saturation Transfer (ST) and -weighted measurements were conducted. The spatial variation in the RF field (B_0) was determined by measuring a flip angle map, using the dual refocusing echo acquisition mode (DREAM) sequence (Nehrke & Börnert, 2012). The flip angles were divided by the nominal flip angle to map the relative irradiation amplitude (relative). The 1H MT MRI measurements were conducted using a saturation RF pulse combined with a Rapid Acquisition with Refocusing Echoes (RARE) sequence. A reference unsaturated MRI image ( and a corresponding saturated image ( ) were acquired at frequency offsets ( ) of 450 ppm and 10 ppm, respectively in order to obtain the . In addition, MRI images were acquired at = 2.7 and -2.7 ppm to obtain the maps and Water Saturation Shift Referencing (WASSR) spectra were acquired to construct a -map (data not shown in this paper). The saturation pulse consisted of a train of pulses with a total duration ( ) of 1 s and a saturation pulse amplitude ( ) of 3 µT. Three sagittal slices with a field-of-view (FOV) of 400 mm x 352 mm, in-plane resolution of 1 mm x 1 mm, slice thickness of 4 mm, slice gap of 2 mm were acquired. SINC pulses were used for excitation and refocusing. The excitation flip angle was 90° and the first refocusing flip angle was 180° followed by 110° pulses. A repetition time ( )
of 6.6 s, an effective echo time (TE\text{eff}) of 80 ms, and a turbo factor (TF) of 82 were used, resulting 
in a total acquisition time of 79.5 s. To assess TGC, semi-solid and liquid volumes, T\textsubscript{2}\text{-weighted} 
anatomical images were acquired using a RARE sequence with 28 axial slices, FOV of 400 mm x 400 mm, in-plane resolution of 0.625 mm x 0.625 mm, slice thickness of 4 mm and inter-slice gap of 1.4 mm. The excitation and refocusing RF pulse angles were the same as for the MT scans. The 
adopted MRI acquisition parameters, namely TR of 755 ms, T\text{eff} of 80 ms, and TF of 65, resulted in 
a total acquisition time of 21 s. Shimming and pulse calibrations were conducted before the MT and 
T\textsubscript{2}\text{-weighted anatomical scans at each measured digestion timepoint. Shimming was performed on 
the stomach area using pencil beam volume with high-order shims.

2.6. MRI data processing and analysis

The TGC was manually delineated in the \(S_0\) and \(S_{sat}\) MT MRI images for each slice at each timepoint 
using the Medical Image Processing And Visualization (MIPAV) software 11.0.3. (National Institutes 
of Health, Bethesda, MD, USA) and stored as a binary mask. All further image processing and 
calculations were conducted in MATLAB 2019b (MathWorks, Massachusetts, USA). The masks were 
used to extract the gastric content. Rigid (translation and rotation) and non-rigid (deformation) 
motion of the stomach were corrected for by using the robust principal component analysis (RPCA) 
approach (Bie et al., 2019), combined with affine image registration. The image correction was 
performed after applying the TGC mask on the images because this provided better spatial 
alignment of the gastric content between the reference \(S_0\) and \(S_{sat}\) MRI images compared to 
performing the correction on the whole FOV. In short, RPCA was used to decompose the \(S_0\) and \(S_{sat}\) 
(including at \(\Delta \pm 2.7\) ppm) images into a low-rank and sparse component of the image to separate 
the contrast from the motion. The motion-free low-rank component was recomposed into the 
\(S_0\) and \(S_{sat}\) images, and the average of these images was calculated to obtain a motion-free 
reference image. The reference image was used for re-alignment of the original motion-corrupted 
images (Fig. S2 in SI). The re-aligned gastric content images were used to obtain masks of the 
low- and high-intensity image voxels, attributed to the semi-solid and liquid components, 
respectively. This segmentation was achieved via automatic intensity-thresholding using the multi-
thresh function (Otsu’s method) with two levels in MATLAB, similar to the approach used on \textit{in vitro} 
images of milk digestion (Mayar et al., 2024). Otsu’s method finds the optimal threshold value that
groups the voxels into separate classes for which the within-class variance is minimised. Voxels
with intensities below or above the second threshold level, which represented 40-50% of the
maximum image intensity, were respectively categorized as low- or high-intensity voxels, and
attributed to semi-solid or liquid fractions (Fig. S3 in SI). The low-intensity voxels were saved as a
binary mask and applied to the re-aligned MT images to calculate the $MTR$ of the semi-solid content
for each slice using Eq. 1, from which we can see that the $MTR$ ranges between 0 and 1.

$$MTR = 1 - \frac{S_{\text{tot}}}{S_0}$$  \hspace{1cm} \text{Eq. 1}

The experimental $MTR$ values of the semi-solid content were corrected by omitting values that were
<0 and ≥1, which are likely caused by gastric content mixing. The corrected data for each slice
was used to calculate the mean and SD of the $MTR$ over all the low-intensity (semi-solid) voxels for
each time point and participant. The $MTR$ in the liquid fraction is negligible because of the high $^1$H
mobility. The SD of the $MTR$ map was calculated as a measure of the spatial variation in the semi-
solid gastric content $MTR$ values.

Gastric content masks of the $T_2$-weighted scans in the axial plane were obtained in the same way
as described for the MT scans. These masks were used to calculate the TGC volume by multiplying
the total number of voxels by the individual voxel volume, taking into account the slice thickness
and the inter-slice gap. GE was defined as the decrease in TGC volume over time. The semi-solid
and liquid masks were obtained in the same manner as for the MT data and were subsequently
used to calculate the corresponding volumes.

2.7. Statistical analysis

Data are reported in the form mean ± SD unless stated otherwise. All statistical analysis were
performed using RStudio 4.3.1 (PBC, Boston, MA). The threshold for statistical significance was set
at $p = 0.05$. Normality of the data was checked with quantile-quantile plots of the residuals. A
Sidak-adjusted Linear Mixed Model (LMM) was used to test for effects of time, treatment and a
treatment-by-time interaction on the $MTR$ of the gastric content. Time and treatment (milk
products) were added as fixed effects and participants were included as a random effect. Outliers
in the MT data were identified and removed using the 3*IQR (interquartile range) criterion method
(Fig. S4 in SI). A LMM was also used to test the effect of time, treatment and treatment-by-time
interaction on the TGC, semi-solid and liquid volumes with the inclusion of baseline TGC volumes as a covariate. For the appetite and well-being ratings, baseline ratings were included as a covariate. In the case of a significant treatment effect, Tukey's HSD post-hoc t-tests were used to compare individual time points. As an exploratory analysis, the effect of sex on the outcomes was tested using a LMM with time and sex as fixed factors, baseline GC volume as a covariate and the participants as a random factor. The two treatments were grouped per sex. The analysis was conducted with and without the inclusion of body size, approximated as weight times height of the participant, as a covariate. Paired t-tests were used to compare LPSM and HPSM with the following measures: the incremental area under the curve (AUC) of the $MTR$, TGC, semi-solid and liquid volume, as well as the $MTR_{max}$ and the change in the $MTR$ between $t = 5$ min and $t = 95$ min ($\Delta MTR$).

3. Results

3.1. TGC, semi-solid and liquid volume vs. digestion time

The $^1$H MRI $T_2$-weighted images were used to quantify the volume of the TGC and semi-solid or liquid fractions over time (Fig. 2). At baseline, there was only gastric juice present and, at $t = 12$ min, the milk was still in the liquid state. As digestion progressed, low-intensity voxels at the center surrounded by high-intensity voxels at the stomach wall were observed, respectively, corresponding to the semi-solid coagulum or gastric fluid, and indicated in the insets in red or blue.
Figure 2. Example of transversal \(^1\text{H} \text{ MRI} \) -weighted images at baseline and during digestion, showing the emptying of the stomach and the changes in liquid (red) and semi-solid (blue) fractions as shown in the insets on the top right.

The baseline GC volume was 31 ± 18 mL and 35 ± 12 mL for LPSM and HPSM treatments, respectively (\( p = 0.69 \)). After milk ingestion, the TGC volume correspondingly increased to 267 ± 44 mL and 288 ± 40 mL for LPSM and HPSM, respectively, followed by a decrease over time (Fig. 3a). There was a significant effect of treatment on the TGC volume, with lower volumes for LPSM (\( p = 0.044, \text{MD} = 40.3 \text{ mL} \text{ 95\% CI [25.5 - 55.1]} \)). This effect was significant at most timepoints (t = 27 and 57 - 102 min, all \( p<0.05 \)). There was no treatment-by-time interaction effect (\( p = 0.49 \)).

The semi-solid volume (Fig. 3b) decreased linearly with time for both LPSM and HPSM. The treatment effect tended to be significant (\( p = 0.057 \)) with lower volumes for LPSM (\( \text{MD} = 31.8 \text{ mL} \text{ 95\% CI [19.9-43.8]} \)), and the treatment-by-time interaction effect was not significant (\( p = 0.26 \)).

The liquid volume (Fig. 3c) for LPSM decreased with a similar trend as the TGC volume, with lower volumes compared to HPSM from 57 min onwards. The liquid volume for HPSM showed little variation over time. There was no main effect of treatment on the liquid volume (\( p = 0.68 \)), but the treatment-by-time effect tended to be significant with higher liquid volumes for HPSM at \( t \geq 57 \text{ min} \) (\( p = 0.065, \text{MD} = 65.8 \text{ mL} \text{ 95\% CI [43.4 - 88.2]} \)).

The AUC of the TGC (Fig. 3d) and liquid volume (Fig. 3f) were lower for LPSM compared to HPSM (\( p = 0.021 \) and \( p = 0.017 \)). There was a trend towards a lower semi-solid volume for LPSM (\( p = 0.078 \)) (Fig. 3e).
Figure 3. (a) TGC, (b) semi-solid and (c) liquid volumes vs. digestion time for LPSM and HPSM estimated from the -weighted MRI images, along with the respective AUC of the (d) TGC, (e) semi-solid and (f) liquid volumes. Symbols ** and * stand for p<0.01 and p<0.05, respectively. Data are plotted as mean ± SD over all participants. In d-f, individual data for each participant are also shown.

5.3.2. ¹H MT MRI during gastric digestion

The sagittal -weighted images of the abdomen (top), and the corresponding maps overlayed on the -weighted images (middle), are shown in Fig. 4. At baseline and t = 5 min, the gastric content appeared homogeneous within each -weighted image (Fig. 4a). As digestion progressed, the size of the stomach decreased due to GE and the semi-solid coagulum and liquid fractions could be observed. The maps (Fig. 4b) show that the at baseline was low, which is expected for the fasted state, where the gastric content is mainly composed of gastric juice. The at t = 5 min after the start of ingestion was higher than that at baseline due to the presence of the milk proteins, and subsequently increased with digestion for both LPSM and HPSM. The histograms of the values for each map (Fig 4c) were characterized by a narrow unimodal distribution at t = 5 min, while such distribution broadened and shifted towards higher values at longer digestion times.
The mean $MTR$ increased over time for both LPSM and HPSM ($p<0.001$, Fig. 5a). The MD between LPSM and HPSM was 16% (95% CI [10-21]). The $MTR$ values of HPSM appeared higher than those of LPSM from 35 to 65 min. However, no significant treatment or treatment-by-time interaction effects were found ($p = 0.15$ and $p = 0.58$, respectively). The spatial variation of the $MTR$ values also increased with time, which may indicate an increase in the heterogeneity of the semi-solid gastric content with digestion (Fig. 5b), in agreement with the observations from the histograms in Fig. 4. In contrast to the $MTR$ values, the average $rR$, and its spatial variation over the voxels used for calculating the $MTR$ maps, decreased with the digestion time from 100 ± 15% at $t = 5$ min to 87 ± 9% at $t = 95$ min (Fig. S5 of SI). As demonstrated in Fig. 5c-e and Fig. S6 in SI, the inter-individual variation in the $MTR$ values was large, and there was no significant difference in the $\Delta MTR$ ($p = 0.29$), AUC $MTR$ ($p = 0.48$) and $MTR_{\text{max}}$ ($p = 0.15$) between LPSM and HPSM. The baseline $MTR$ value tended to be lower ($p = 0.057$) for the LPSM ($MTR = 0.08 \pm 0.02$) compared to HPSM ($MTR = 0.10 \pm 0.04$) treatment. However, there was no correlation between the baseline $MTR$ values and the AUC $MTR$ or $MTR_{\text{max}}$ (all $r<0.35$ and $p>0.3$; see Table S1).
Figure 4. (a) T$_2$-weighted sagittal MRI images of the abdomen at baseline, t = 5 min after ingestion of 300 g of LPSM or HPSM and at 30 min intervals until t = 95 min. The $^1$H MRI intensities are scaled to the maximum intensity for each individual image. Corresponding (b) color-coded maps and (c) histograms in which the y-axis is scaled to the gastric content volume for each time point. Data are from one randomly selected participant.
Figure 5. (a) Mean and (b) spatial variation, determined by the SD of the $^1$H MTR values of the semi-solid voxels over time. (c) The change in MTR from 5 to 95 min after milk ingestion ($\Delta MTR = (t=95) - (t=5)$). (d) The AUC and (e) the ... data for each participant are also shown.

3.3. Exploratory analysis on the effect of sex on the outcomes

Exploratory analysis showed that the TGC volume and liquid volume over time were higher for females compared to males ($p<0.001$, $p = 0.025$ and $p = 0.026$, respectively, Fig. S7 in SI). There was no difference in the semi-solid volume between males and females ($p = 0.12$). The male and female participants had an average body size, estimated as weight times the height, of $(1.4 \pm 1.7) \times 10^4$ and $(1.1 \pm 0.9) \times 10^4$ kg\*cm, respectively. After accounting for the effect of body size, the
effect of sex on the $MTR$, TGC volume and liquid volume was no longer significant ($p=0.46$, 0.28 and 0.74, respectively).

3.4. Appetite and well-being ratings

The appetite and well-being ratings over time are reported in Fig. S8 in SI. Participants reported a higher level of hunger and appetite ($p < 0.001$) and a lower level of fullness ($P<0.05$) for HPSM compared to LPSM. For hunger and appetite, the effect was driven by most time points ($p <0.05$), whereas for fullness, the effect was driven by time points 42 min and 57 min ($p = 0.02$ and $p = 0.048$, respectively). There was no treatment effect on thirst, bloating or nausea ($p = 0.31$, $p = 0.29$ and $p = 0.90$, respectively). There was a significant treatment-by-time effect with higher ratings of nausea at $t\geq 57$ min for HPSM compared to LPSM ($p = 0.04$). However, this effect was mainly driven by 2 participants who reported 20 points higher nausea scores for HPSM compared to LPSM, whereas the other participants reported nausea scores of around 0 throughout the digestion for both milk products. Therefore, no firm conclusions can be drawn from this.

4. Discussion

The objective of this study was to assess the feasibility of using $^1$H MT MRI for monitoring gastric milk protein coagulation in vivo in humans using LPSM and HPSM as test-products. The TGC, semi-solid and liquid volumes were compared between the two products to investigate the effect of heat treatment on the GE dynamics.

4.1. GE dynamics

We found that the TGC volume remained higher for a longer duration for HPSM compared to LPSM. This suggest a slower GE with more extensive heat treatment. Additionally, the semi-solid and liquid volumes vs. digestion time appeared to be higher for HPSM compared to LPSM, although these differences were not statistically significant.

These findings contradict our initial expectation, as previous in vitro (Li et al., 2022; Mulet-Cabero et al., 2019) and in vivo animal (Ahlbom et al., 2023; Ye et al., 2019) studies have demonstrated
that heat treatment typically results in a coagulum with a looser and softer consistency during gastric digestion, which has been suggested to potentially lead to a faster GE. Ahlbom et al. (2023) showed that, for a 500 mL load of milk, the TGC, coagulum, total protein and coagulated protein emptied faster for UHT compared to pasteurized milk during gastric digestion in pigs. These differences were attributed to the weaker and more open coagulum structure observed for UHT milk. In contrast, Ye et al. (2019) reported that the wet and dry weight of the coagulum were higher for UHT compared to pasteurized milk in rats at 30 and 120 min after milk ingestion, but slightly lower at 240 min. This suggests that the volume and moisture content of the coagulum from UHT milk is higher in the first 120 min of digestion, aligning with the higher semi-solid and liquid volume found for HPSM in the present study. The higher liquid volume for HPSM may indicate a higher moisture content which, in turn, could be attributed to a coagulum microstructure with more abundant and larger voids (Ye et al., 2016). Barbé et al., (2013) found that the mean retention time of chromium in the stomach in pigs was longer for heated (10 min at 90 °C) compared to unheated rehydrated ultra-low heat skim milk powder, which may suggest a slower emptying of milk upon heat treatment. Overall, in vitro and in vivo studies in animals have shown that high temperature or prolonged heat treatment result in a looser and softer milk protein coagulum during gastric digestion, but there is no consistent information on how this affects GE.

A recent in vivo study in humans showed that GE was slower for UHT compared to pasteurized milk, in line with the outcome of our study (Milan et al., 2024). They also showed that the concentration of essential AAs in the blood was higher for UHT compared to pasteurized milk. While other in vivo studies in humans (Horstman et al., 2021; Lacroix et al., 2008) did not report a difference in AA concentrations in blood following the consumption of UHT and pasteurized milk, Lacroix et al. (2008) did report an enhanced transfer of dietary nitrogen into serum AA and protein pools for UHT compared to pasteurized milk. They proposed that a softer coagulum and more rapid GE could explain the observed difference. However, as shown in the present study and by Milan et al. (2024), more extensive heat treatment resulted in a slower GE. This suggests that the differences in plasma AA concentrations observed after consumption of differently heated milk products is more likely caused by the higher gastro-intestinal hydrolysis level of denatured WPs from UHT milk than by differences in GE and coagulation dynamics.
4.2. Interpretation of MT MRI data

Following ingestion, the $MTR$ was initially low but, as digestion progressed, a notable increase in the $MTR$ was observed for both LPSM and HPSM (Fig. 5). Right after ingestion, the milk is in a liquid state and, consequently, the macromolecular mobility is still high, resulting in a low $MTR$ (Henkelman et al., 2001; van Zijl et al., 2018). As digestion proceeds, a transition from a liquid to semi-solid state occurs, primarily driven by the aggregation of caseins induced by pepsin and stomach acid (Huppertz & Chia, 2021). This transition to a semi-solid state can cause a decrease in the macromolecular mobility, leading to stronger inter- and intra-molecular dipolar interactions, which are the drivers of the $^1H$ MT effect in MRI (Henkelman et al., 2001; van Zijl et al., 2018; Zhou et al., 2023). In our preceding study (Mayar et al., 2024), a similar increase in the $MTR$ was observed for LPSM during semi-dynamic in vitro gastric digestion. The in vitro $MTR$ data was compared with visual and rheological assessment of the coagula, which confirmed that the increase in $MTR$ corresponded to an increase in the storage modulus and, hence, in the stiffness of the coagulum. The agreement between the in vitro and in vivo data for LPSM, alongside the significant $MTR$ variation vs. digestion time, confirmed the suitability of MT MRI for monitoring gastric milk protein coagulation in vivo. However, we did not observe an effect of heat treatment on the $MTR$ over time. Interestingly, this is in contrast with our previous in vitro study (Mayar et al., 2024) where, based on visual assessment, the coagulum of HPSM appeared more loose compared to that of LPSM. This difference was also reflected in the $MTR$ values, which were lower for HPSM compared to LPSM beyond 50 min of gastric digestion.

The $MTR$ and GE data altogether suggest that the effect of heat treatment on gastric coagulation may be different in humans compared to what has been observed in in vitro and in vivo animal models. Gastric coagulation of milk is highly affected by pH and pepsin activity, which can vary both between and within individuals (Fadda et al., 2022; Semple et al., 2001). Furthermore, gastric fluid volume in the fasted state also varies between and within individuals (Grimm et al., 2018; Roelofs et al., 2024), and has previously been shown to affect the formation of a fat layer during gastric milk digestion (Camps et al., 2021). Accordingly, the gastric fluid volume may also affect gastric milk coagulation. In this study, the baseline $MTR$ values tended to be lower for the LPSM compared to the HPSM treatment, which could have affected the coagulation process and, hence, the $MTR$. However, there was no correlation between baseline $MTR$ values and the AUC $MTR$.
or $MTR_{max}$ values. Consequently, additional research with larger sample sizes is required to provide more insights into the coagulation process.

A recent study assessed gastric milk coagulation in women experiencing gastro-intestinal (GI) complaints and in a control group after milk consumption by calculating image texture metrics, namely homogeneity, contrast, busyness, and coarseness, for the $T_2$-weighted anatomical images (van Eijndatten et al., 2023). The decrease in homogeneity, and increase in contrast and coarseness, were associated with the coagulation process. While such image texture metrics show promise for monitoring gastric milk coagulation, they need to be verified with MRI data of in vitro digestion samples, analogously to what we have done for the $MTR$ parameter.

4.3. Challenges in acquisition and quantification

Conducting MT measurements in vivo in humans is challenging due to artifacts caused by breathing motion and gastric motility. To construct the $MTR$ maps, the $S_0$ and $S_{sat}$ images were acquired separately in different breath holds. Although breath holding minimizes breathing-related motion artifacts within an image, it does not account for differences between the $S_0$ and $S_{sat}$ images. Differences in both the position and shape of the stomach were observed, with the latter being caused by gastric contractions. These differences were corrected using rigid and non-rigid image registration. However, in certain cases, gastric contractions and mixing resulted in differences in the content of individual voxels between the $S_0$ and $S_{sat}$ images. For example, some voxels contained low-intensity components in the $S_0$ image, arising from semi-solid fractions, but high-intensity (liquid) components in the $S_{sat}$ image, leading to negative $MTR$ values. These values were excluded from the $MTR$ maps and from the corresponding calculation of the mean $MTR$ over the semi-solid voxels. In future applications it is preferable to work on reducing the acquisition time of the scans to enable acquisition of both the $S_0$ and $S_{sat}$ images in one breath hold. This could help to minimize the sensitivity to mixing effects, and to improve the accuracy of the $MTR$ measurements.

In this work, the $^1$H MT MRI scans were acquired using a RARE sequence with a 90° RF excitation flip angle and $T_2$-weighting, with an acquisition time of around 19 s per image. In humans the stomach typically contracts about three times per minute (Lu et al., 2022), which suggests that the $S_0$ and $S_{sat}$ scans may have been acquired during two different contractions. The acquisition can be accelerated by replacing the RARE sequence with a faster sequence, such as a Gradient Recalled
Echo (GRE) sequence. However, faster image acquisition schemes often come at the cost of lower signal-to-noise ratios (SNR) and poorer contrast. This could make it challenging to accurately delineate the gastric content and to separate liquid and semi-solid components using intensity thresholding. Therefore, further optimization of the scan parameters is required to achieve faster measurements, while maintaining a high SNR and good contrast. Faster measurements are also beneficial for covering a whole stomach volume. In this study, with a scan time of 19 s, only three sagittal slices could be acquired with a thickness and interslice gap of 4 and 2 mm, respectively, covering 16 mm in the left-to-right direction. This might not be representative of the whole gastric content, and is a limitation of this feasibility study.

In this study, the intensity thresholding method that we previously applied to in vitro $T_2$-weighted MRI images (Mayar et al., 2023, 2024) was used to identify low- and high-intensity voxels in in vivo images. The low- and high-intensity voxels were attributed to more semi-solid and liquid gastric content, respectively, and were used to quantify their respective volumes over time. It is worth noting that with this approach a threshold value is determined even within 12 min after milk ingestion when milk is still in a liquid state. This stems from the lack of direct mixing between ingested milk and the baseline gastric content, primarily composed of gastric juice. This leads to the formation of a thin layer of baseline gastric content on top of the milk. The baseline gastric content likely comprises gastric juice, based on its higher intensity compared to the ingested milk in the $T_2$-weighted MRI images. The intensity thresholding will then separate the liquid milk from this high-intensity layer. Therefore, in this study, the obtained semi-solid and liquid volumes were considered from the second timepoint onwards, where coagulation became clearly visible.

A potential limitation of MRI is that it usually requires participants to be in a supine position, which affects the position of the stomach due to gravity. This could lead to a difference in fluid dispersion throughout the stomach, thereby affecting gastric coagulation and emptying (Holwerda et al., 2016). However, relative differences are expected to remain the same (Jones et al., 2006)
4.4. Inter-individual variation

This study included both male and female participants for better generalizability. The $MTR$, TGC, and liquid volumes were higher in females as compared to males. However, after accounting for body size, no significant differences remained. This indicates that these differences are related to body size and may not be inherently sex-specific. Previous studies have demonstrated slower GE in females compared to males (Camps, de Graaf, et al., 2018; Gill et al., 1987; Hermansson & Sivertsson, 1996). However, none of these studies included body size as a factor in their statistical analysis. Camps et al. (2018) did find a weak correlation ($r = 0.266, p < 0.05$) between body size and TGC volume, but they concluded that this was not strong enough to explain the effect of sex on TGC volume. Previous research has reported differences in pepsin activity and in gastric pH between males and females (Lindahl et al., 1997), which could also influence gastric coagulation and emptying. Therefore, more research is warranted to better understand the effect of different factors, including body size and (sex) hormones, on gastric digestion.

5. Conclusions

We have demonstrated the potential of $^{1}$H MT MRI as a novel non-invasive method for measuring gastric milk protein coagulation in humans. The $MTR$ parameter, which is a marker of coagulum consistency, can be obtained from two rapid scans of less than 20 s each. By combining conventional $T_2$-weighted anatomical images with MT measurements, the GE of total, semi-solid and liquid gastric content, as well as changes in the coagulum structure, could be assessed in vivo.

The $MTR$ of LPSM increased during gastric digestion, which reflected milk protein coagulation and was in agreement with previous data from a semi-dynamic in vitro model. Interestingly, contrary to the in vitro data, no difference was found in the $MTR$ between LPSM and HPSM in vivo. Moreover, gastric content volumes over time were higher for HPSM compared to LPSM, indicating a slower GE upon heat treatment. These findings demonstrate that the effect of heat treatment on gastric milk protein digestion may be different in humans compared to what has been observed in in vitro and animal models. This highlights the importance of conducting in vivo studies in humans when investigating effects of heat treatment on gastric milk digestion. Our innovative approach holds promise for investigating the effect of various heat treatments or the presence of lipids on gastric milk protein coagulation and emptying dynamics. Moreover, it opens the way for exploring gastric
digestion of a variety of (semi)-solid foods, including yoghurt, cheeses and protein-rich foods with different micro- and macrostructures. Insights from such studies can not only improve our understanding of how food processing, composition, and structure affect gastric digestion, but may also contribute to the improvement of in vitro digestion models.
