Abstract

Introduction

Increased vitamin D levels, as reflected by 25OHD measurements, has been proposed to protect against Covid-19 disease based on *in-vitro*, observational, and ecological studies. However, vitamin D levels are associated with many confounding variables and thus associations described to date may not be causal. Vitamin D MR studies have provided results that are concordant with large-scale vitamin D randomized trials. Here, we used two-sample MR to assess the effect of circulating 25OHD levels on Covid-19 susceptibility.

Methods and findings

Genetic variants strongly associated with 25OHD levels in a 443,734-participant genome-wide association study (GWAS) were used as instrumental variables. GWASs of Covid-19 susceptibility and severity from the Covid-19 Host Genetics Initiative were used as outcomes. Cohorts from the Covid-19 Host Genetics Initiative GWAS included up to 14,134 individuals with Covid-19, and 1,284,876 with Covid-19, from 11 countries. Analyses were restricted to individuals of European descent when possible. Using inverse-weighted MR, genetically increased 25OHD levels by one standard deviation on the logarithmic scale had no clear association with Covid-19 susceptibility (OR = 0.97; 95% CI: 0.95, 1.10; P=0.613), hospitalization (OR = 1.11; 95% CI: 0.91, 1.35; P=0.299), and severe disease (OR = 0.93; 95% CI: 0.73, 1.17; P=0.531). We used an additional 6 meta-analytic methods, as well as sensitivity analysis after removal of variants at risk of horizontal pleiotropy, and obtained similar results. These results may be limited by weak instrument bias in some analyses. Further, our results do not apply to individuals with vitamin D deficiency.

Conclusion

Our results do not support that patients be advised to take vitamin D supplementation to protect against Covid-19 outcomes. Further, other therapeutic or preventative avenues should be given higher priority for Covid-19 randomized controlled trials.

Author Summary

- *Why was this study done?*

- The Covid-19 pandemic is the most important public health emergency in recent memory.
- Vitamin D levels have been associated with Covid-19 outcomes in multiple observational studies, though confounders are likely to bias these associations.
- By using genetic instruments which are not affected by such confounders, Mendelian randomization studies have steadily obtained results consistent with vitamin D supplementation randomized trials and may also be used in the context of Covid-19.

- *What did the researchers do and find?*

- We used the genetic variants obtained from the largest cohort of Covid-19 cases and controls, and the largest study on genetic determinants of vitamin D levels.
- We used Mendelian randomization to combine these genetic variants to estimate the effect of increase vitamin D on Covid-19 outcomes, while controlling for confounders.
- In multiple analysis, our results consistently showed no evidence for an association between vitamin D levels and Covid-19 susceptibility, hospitalization, or severe disease.

- *What do these findings mean?*

- Vitamin D is a highly confounded variables, and traditional observational studies are at high risk of biased estimates.
- We do not find evidence that vitamin D supplementation would improve Covid-19 outcomes.
- Given mendelian randomization's past record with randomized controlled trial, other therapeutic and preventative avenues should be prioritized for Covid-19 randomized trials.

Introduction

SARS-CoV-2 infection has killed hundreds of thousands of individuals and has led to the largest economic contraction since the Great Depression[1]. Therefore, therapies are required to treat severe Covid-19 disease and to prevent its complications. Therapeutic development, in turn, requires well-validated drug targets to lessen Covid-19 severity.

Recently, vitamin D status, as reflected by 25-hydroxy-vitamin D (25OHD) level has been identified potentially actionable drug target in the prevention and treatment of Covid-19[2]. As the pre-hormone to the biologically active calcitriol, 25OHD has been epidemiologically linked to many health outcomes[3,4]. Given calcitriol's recognized *in-vitro* immunomodulatory role[5], as well as observational and ecological studies on measured 25OHD blood levels and Covid-19[6,7], the vitamin D pathway might be a biologically plausible target in Covid-19. This could be of public health importance, given that the prevalence of vitamin D insufficiency is high in most countries, and that more than 37% of elderly adults in the USA take vitamin D supplements[8]. Further, 25OHD supplementation is inexpensive and reasonably safe—thus providing a potential avenue to lessen the burden of the SARS-CoV-2 pandemic.

However, observational studies on 25OHD are prone to confounding and reverse causation bias. Confounding happens when the relationship between exposure (25OHD) and the outcome (Covid-19) is influenced by an unobserved, or improperly controlled common causes. Reverse causation happens when the outcome itself is a cause of the exposure. Likewise, conclusions drawn from *in-vitro* may not be applicable *in-vivo*. Accordingly, randomized controlled trials (RCTs) on 25OHD supplementation have been undertaken to test their effect on disease outcomes where observational studies have supported a role for 25OHD level. However, across endocrinology, respiratory, cardiology, and other specialties, these trials have most often have failed to show clinical benefits[9–11]. Some RCTs have even shown detriment to 25OHD supplementation[12]. In the field of infectious diseases, an individual patient data meta-analysis of randomized controlled trial of 25OHD supplementation[13] showed some benefit to prevent respiratory tract infections (OR 0.80, 95% CI: 0.69 to 0.93). However, this effect was driven by generally benign upper respiratory tract infections, and was not observed in lower respiratory tract disease (OR: 0.96, 95% CI: 0.83 to 1.10) and even showed numerically worse all-cause mortality (OR: 1.39, 95% CI: 0.85 to 2.27). Likewise, a recent trial on sepsis obtained a numerically higher mortality rate in patients who received 25OHD supplementation[14]. For now, we are only aware of one RCT on vitamin D supplementation in Covid-19[15], which showed less intensive care unit admissions in the treatment arm. However, the combination of its small size (n=75), varying follow-up time for mortality, and open label design put it at high risk of bias and is unlikely to be able to inform physicians and public health authorities on vitamin D supplementation. Hence, while RCTs can control for confounding and provide unbiased estimates of the effect of 25OHD supplementation in Covid-19, large well-designed RCTs require considerable resources and time.

Mendelian randomization (MR) is a genetic epidemiology method that uses genetic variants as instrumental variables to infer the causal effect of an exposure (in this case 25OHD level) on an outcome (in this case, Covid-19 susceptibility and severity)[16]. MR overcomes confounding bias since genetic alleles are randomized to the individual at conception, thereby breaking associations with most confounders. Similarly, since genetic alleles are always assigned prior to disease onset, they are not influenced by reverse causation. MR has been used in conjunction with proteomics and metabolomics to [15]prioritize drug development and repurposing, and support investment in RCTs which

have a higher chances of success[17,18]. In the case of vitamin D, MR has been able to provide causal effect estimates consistently in line with those obtained from RCTs[9,19–23], and may support investments in 25OHD supplementation trials in Covid-19, if a benefit was shown. Further, since MR results can be generated rapidly, such evidence may provide interim findings while awaiting RCT results.

However, MR relies on several core assumptions[24]. First, genetic variants must be associated with the exposure of interest. Second, they should not affect the outcome except through effects on the exposure (also known as lack of horizontal pleiotropy). Specifically, MR also assumes that the relationship between the exposure and the outcome is linear. However, this assumption still provides valid results when studying population-level effects[25]. Third, genetic variants should not associate with the confounders of the exposure-outcome relationship. Of these, the most problematic is the second assumption. Yet, in the case of 25OHD, many of its genetic determinants reside at loci that harbour genes whose roles in 25OHD production, metabolism and transport are well known[26]. Leveraging this known physiology can help to prevent the incorporation of genetic variants that could lead to horizontal pleiotropy. Lastly, MR assumes linearity of causal effect.

Here, we used genetic determinants of serum 25OHD from a recent genome-wide association study (GWAS) and meta-analysis of more than 443,734 participants of European ancestry[27] in an MR study to test the effect of increased 25OHD level on Covid-19 susceptibility and severity.

Methods

We used a two-sample MR approach to estimate the effect of 25OHD levels on Covid-19 susceptibility and severity. In two-sample MR[28], the effect of genetic variants on 25OHD and on Covid-19 outcomes are estimated in separate GWASs from different populations. This allows for increased statistical power by increasing the sample size in both the exposure and outcome cohorts.

Our study did not employ a prospective protocol. Analyses were first planned and performed in July 2020 and updated following peer-review in December 2020. Three major changes were made during the update. First, we used the most up to date Covid-19 Host Genetics Initiative (Covid-19 HGI) genome-wide association study summary statistics. These were made available during the peer-review process. Second, to alleviate potential selection and collider bias, we modified the outcome phenotypes to include population controls. Lastly, we performed additional mendelian randomization sensitivity analyses to check for the robustness of our results. The latter two modifications were made at the request of peer-reviewers.

Choice of 25OHD genetic instruments

To find genetic variants explaining 25OHD levels[27], we used a GWAS from our group, which is the largest published GWAS of 25OHD levels. Importantly, this meta-analysis controlled for vitamin D levels season of vitamin D measurement to obtain genetic variants significantly associated with 25OHD levels. From the list of conditionally independent variants provided, we further selected SNPs whose effect on 25OHD level was genome-wide significant ($P < 5 \times 10^{-8}$), minor allele frequency was more than 1%, and with linkage disequilibrium coefficients (r^2) of less than 5%. For SNPs that were not available in the outcome GWAS or with palindromic alleles of intermediate frequency (between 42% and

58%), we used the LDlink tool[29] to find genetic proxies in the European 1000 Genomes dataset (excluding Finnish populations) using linkage disequilibrium r^2 of 90% or more.

Covid-19 outcome definitions and GWASs

We used the Covid-19 HGI phenotype definitions and GWAS summary statistics for Covid-19 susceptibility, hospitalization, and severe disease outcomes[30]. The susceptibility phenotype compared confirmed Covid-19 cases, defined as laboratory confirmed of SARS-CoV-2 infection based on RNA or serology tests, or by electronic health records (using International Classification of Diseases or physician notes), with controls defined as any individuals in each cohort without a history of Covid-19. The hospitalized phenotype compared cases defined as hospitalized patients with Covid-19, and controls as any individuals in each cohort without a hospitalization with Covid-19. The severe disease phenotype cases were defined as hospitalized individuals with Covid-19 and requiring respiratory support. Respiratory support was defined as intubation, CPAP, BiPAP, continuous external negative pressure, or high flow nasal cannula. Controls for the severe Covid-19 phenotype were defined as any individuals without severe Covid-19. These three outcome phenotypes are referred to as C2, B2, and A2, respectively, in the Covid-19 HGI documentation.

For our study, we used the October 20th, 2020 Covid-19 HGI fixed effect meta-analysis of GWAS from up to 22 cohorts, performed in up to 11 countries. Every participating cohort was asked to provide summary statistics from a GWAS on the above three outcomes, and including the following non-genetic covariates: age, sex, age*age, age*sex, 20 genetic principal components, as well as any locally relevant covariates at the discretion of participating studies (e.g. hospital, genotype panel, etc.). Cohorts were asked to follow common sample and variant quality control, and only performed analysis if they enrolled 100 cases or more. Analyses were done separately for each major ancestry group to further control for population stratification. For the purposes of our study, we used the meta-analysis results from European ancestry cohorts, except for the severe Covid-19 cohort, for which this meta-analysis was not available. Further details on the three phenotypes and participating cohorts are found in [Table 1](#) and [Supplement 1](#).

Primary MR analysis

The effect of 25OHD level on Covid-19 outcomes was obtained for each SNP by using the Wald ratio method. The effect of each SNP was given in standardized log-transformed 25OHD level. Each estimate was meta-analyzed using the IVW method, and we performed variant heterogeneity tests to check robustness of IVW results. Allele harmonization and computations were performed using the TwoSampleMR package[31].

Horizontal pleiotropy sensitivity analysis

We undertook extensive analysis to assess the risk of horizontal pleiotropy (a violation of the second MR assumption). First, we used MR Egger method, which allows for an additional intercept (alpha) term which also provides an estimate of directional horizontal pleiotropy. Given possible instability in MR Egger estimates[32], we also used the bootstrap MR Egger method to meta-analyze the causal effect estimates from each SNP instrument. Further, we used four additional meta-analysis methods known to be more robust to presence of horizontal pleiotropy (at the expense of statistical power): penalised weighted median, simple mode, weighted median, and weighted mode[33].

Second, we restricted our choices of SNPs to those whose closest gene is directly involved in the Vitamin D pathway. These genes have an established role in vitamin D regulation

through its synthesis (*DHCR7/NADSYN1* and *CYP2R1*), transportation (GC), and degradation (*CYP24A1*) (**Supplement 2**). This decreases the risk of selecting a genetic variant that effects Covid-19 outcomes independent of their effect on 25OHD levels.

Third, we used the Phenoscanner tool[34,35] on the remaining SNPs to check for variants associated (at a genome-wide significant threshold of $p=5 \times 10^{-8}$) with phenotypes at risk of affecting Covid-19 outcomes independent of 25OHD, making them at higher risk of horizontal or vertical pleiotropy. Note that vertical pleiotropy, which happens when the Covid-19 outcome is influenced by a phenotype directly in the causal pathway between 25OHD level and Covid-19 outcome, does not violate MR assumptions.

Research Ethics

Each cohort included in this study received their respective institutional research ethics board approval to enroll patients. All information used for this study are publicly available as deidentified GWAS summary statistics.

Results

Choice of 25OHD genetic instruments

We obtained our 25OHD genetic instruments from our previously published GWAS[27] on circulating 25OHD levels in 401,460 white British participants in the UK Biobank (UKB)[36], which was meta-analyzed with a GWAS on 25OHD levels of 42,274 participants of European ancestry[37]. Of the 138 reported conditionally independent SNPs (explaining 4.9% of the 25OHD variance), 100 had a minor allele frequency of more than 1%, of which 78 were directly available in the Covid-19 HGI GWAS summary statistic and had linkage disequilibrium coefficient of less than 5%. Additionally, 3 more variants had good genetic proxies ($r^2 > 90\%$) and were therefore added to our instrument lists, for a total of 81 variants. These explained 4.3% of the variance in 25OHD serum levels. The full list of SNPs used can be found in **Supplement 3**.

Covid-19 outcome definitions and GWASs

Using the Covid-19 HGI results restricted to cohorts of European ancestry, we used a total of 14,134 cases and 1,284,876 controls to define Covid-19 susceptibility, 6,406 cases and 902,088 controls to define Covid-19 hospitalization, and 4,336 cases and 623,902 controls to define Covid-19 severe disease. **Table 1** summarizes the definition and sample size of both the exposure and outcome GWASs. Since the UKB was used in the two phases of the MR study, some overlap between the exposure and the outcome GWASs was unavoidable (**Supplement 1**).

Primary MR analysis

We first used inverse-weighted variance (IVW) meta-analysis to combine effect estimates from each genetic instrument. For a standard deviation increase in log-transformed 25OHD level, we observed no clear effect upon odds of susceptibility (OR = 0.97; 95% CI: 0.85, 1.10; $P = 0.61$). Of note, a one standard deviation increase in 25OHD serum levels translated to a rise of 21.1 nmol/L of 25OHD in the UK Biobank population, a rise that is comparable to what can be achieved with vitamin D supplementation, especially in short courses[38]. Similarly, we observed no significant different in risk of hospitalization (OR = 1.11; 95% CI: 0.91, 1.35; $P = 0.30$) or risk of severe disease (OR = 0.93; 95% CI: 0.73, 1.17; $P = 0.53$) (**Table 2** and **Figure 1**).

Horizontal pleiotropy assessment and sensitivity analysis

Using the MR Egger intercept terms, we do not observe clear evidence of horizontal pleiotropy. While they have less statistical power than IVW meta-analysis, the 6 sensitivity meta-analysis we used also showed no evidence of an effect of 25OHD levels on Covid-19 susceptibility, hospitalization, and severe disease, with each confidence interval crossing the null in the primary analysis using all SNPs (Figure 1 and Supplement 4). Our results are therefore unlikely to be strongly biased by horizontal pleiotropy.

Second, we restricted our analysis to SNPs which reside close to the four genes directly involved in 25OHD metabolism. This left 12 SNPs, explaining 3.2% of 25OHD variation. Using IVW, each standard deviation increase in log-transformed 25OHD was again not associated with a clear effect on Covid-19 susceptibility (OR = 0.962; 95% CI: 0.83, 1.11; P = 0.594), hospitalization (OR = 1.07 [95% CI: 0.78, 1.47]; P = 0.668) and severe disease (OR = 0.869; 95% CI: 0.635, 1.19; P = 0.378). For the three phenotypes, the MR Egger intercept term did not support bias from directional horizontal pleiotropy.

Lastly, we used the Phenoscanner[34,35] tool to check if the SNPs used in the MR study were associated with other phenotypes. Using Phenoscanner, rs11723621 was associated with white blood cell level, and rs6127099 was associated with glomerular filtration rate. In both cases, the effect on each phenotype was mild compared to their effect on 25OHD level, as rs11723621 explained less than 0.03% of the variance in white blood cell counts, and rs6127099 explained less than 0.001% of the glomerular filtration rate variance[39,40]. Removing these SNPs from the 12 SNPs above further decreased the proportion of 25OHD variance explained to 1.7%. While confidence intervals widened, effect estimates when restricting our analysis to these SNPs remained null for susceptibility (0.797; 95% CI: 0.77, 1.23; P=0.798), hospitalization (1.09; 95% CI: 0.681, 1.75; P=0.714), and severe disease (0.91; 95% CI: 0.54, 1.55; P=0.73).

Genetic instruments heterogeneity

Overall, our results showed little evidence of heterogeneity of effect between our genetic instruments. We nonetheless observe that for at least one of the analyses we would have rejected the null hypothesis of lack of heterogeneity in the Covid-19 hospitalization phenotype. However, given the large number of hypothesis tested, this may be due to chance.

Discussion

In this large-scale MR study, we found that genetically increased 25OHD levels did not protect against Covid-19 susceptibility, hospitalization, or severity. This lack of effect was consistent across phenotypes, sensitivity analyses, and choice of genetic instruments. These findings highlight the confounded association between vitamin D and Covid-19 due to factors such as older age, institutionalization, or medical comorbidities, that are all linked to lower vitamin D levels and cannot be controlled for even when using advanced statistical adjustments. Therefore, in contrast to observational studies, our findings do not support vitamin D supplementation to prevent worse Covid-19 outcomes. Further, while a small randomized trial showed benefit of vitamin D supplementation, this trial used a flawed endpoint and a small sample size, and it is therefore unable to invalidate our results.

Our study's main strength is MR's track record in the study of vitamin D, with multiple studies like ours having provided results consistent with RCTs in multiple medical conditions [9–11,20–23,41,42]. Our study also leverages the largest cohort of Covid-19 cases and controls currently available (even outside of genetic studies) and the largest

study on genetic determinant of 25OHD levels to date. Using these data sources, we were able to obtain results robust to multiple sensitivity analysis and MR methodology.

Our study still has limitations. First, our results do not take true vitamin D deficiency into account, and it remains possible that truly deficient patients may benefit from supplementation for Covid-19 related purposes. However, when comparing previous results from MR studies and RCTs, we do not expect a large impact even in this population. Second, our study may suffer from weak instrument bias, especially the sensitivity analyses restricted to smaller sets of genetic instruments. In two-sample MR, this bias would pull our estimates towards the null. Nonetheless, similar studies have been able to use MR to establish an association between 25OHD levels and other disease (most notably multiple sclerosis[26]), suggesting that these instruments are strong enough to find associations. Further, given the large percentage of shared individuals from the UK Biobank between the vitamin D exposure GWAS[27] and the severe Covid-19 phenotype, this analysis is close to a one-sample MR, which would show bias towards the observational studies effect. Given that this analysis also shows largely null effects, we do not suspect that weak instruments bias is a significant issue in our results. Third, given that vitamin D levels are affected by season (with higher levels after sunlight exposure), even if our SNP-instruments were obtained from a GWAS that controlled for season of blood draw, there is still a chance for effect attenuation by averaging the effect of 25OHD levels on Covid-19 over all seasons. Nevertheless, the size of this bias is likely small, and its direction remains unclear. Fourth, our MR analyses assumes a linear exposure-outcome relationship. While this may slightly bias our results, simulation studies have previously shown that this assumption provides adequate results when looking at a population effect[25]. Therefore, for the purpose vitamin D supplementation RCT prioritization, our conclusions should still be valid. Lastly, as we only studied the effect of 25OHD and Covid-19 in individuals of European ancestry, and it remains possible that 25OHD levels might have different effects on Covid-19 outcomes in other populations. However, previous RCTs on vitamin D supplementation have given similar results in populations of various ancestries[41,42].

In conclusion, using a method that has consistently replicated RCT results for 25OHD outcomes in large sample sizes, we find no evidence to support a protective role for vitamin D supplementation in Covid-19 outcomes. Most importantly, our results suggest that investment in other therapeutic or preventative avenues should be prioritized for Covid-19 randomized controlled trials.

Acknowledgement

Phenotype	Source of genetic variants	
	Cohort	Participants
25OHD circulating levels	Manousaki <i>et al</i> [27]	Meta-analysis of two 25OHD GWAS: - 401,460 adult white British participants from the UKB[36] - 42,274 from an international consortium of adult individuals of European ancestry[37]
Covid-19 susceptibility	Susceptibility	Meta-analysis of 22 GWAS performed in individuals of European ancestry from 11 countries: - Cases: 14,134 individuals with Covid-19 by laboratory confirmation, chart review, or self-report - Controls: 1,284,876 individuals without confirmation or history of Covid-19
Covid-19 severity	Hospitalized	Meta-analysis of 13 GWAS performed in individuals of European ancestry from 11 countries: Cases: 6,406 hospitalized individuals with Covid-19 Controls: 902,088 without hospitalization with Covid-19
	Severe Disease	Meta-analysis of 12 GWAS performed in individuals of European ancestry from 9 countries: - Cases: 4,336 Covid-19 infected hospitalized individuals who died or required respiratory support (intubation, CPAP, BiPAP, continuous external negative pressure, high flow nasal cannula). - Controls: 623,902 without severe Covid-19

Table 1: Sources of data for the analysis. Covid-19 susceptibility and severity outcomes are taken from the Covid-19 HGI[30]. See [Supplement 1](#) for details on cohorts of Covid-19 susceptibility and severity phenotypes.

Outcome	nSNPs	IVW OR (95% CI)	IVW p-value	IVW SNP Heterogeneity p-value	Egger alpha	Alpha p-value
25OHD primary analysis with all SNPs						
Susceptibility	81	0.97 (0.85, 1.10)	0.613	0.008	0.003 (-0.004, 0.009)	0.432
Hospitalization	81	1.11 (0.91, 1.35)	0.299	0.066	0.0002 (-0.010, 0.011)	0.970
Severe disease	81	0.93 (0.73, 1.17)	0.531	0.126	0.010 (-0.002, 0.022)	0.107
25OHD sensitivity analysis restricted to genes in the vitamin D pathway						
Susceptibility	12	0.96 (0.83, 1.11)	0.594	0.160	0.005 (-0.021, 0.032)	0.702
Hospitalization	12	1.07 (0.78, 1.47)	0.668	0.004	0.031 (-0.027, 0.088)	0.323
Severe disease	12	0.87 (0.64, 1.19)	0.378	0.105	0.056 (0.006, 0.106)	0.054
25OHD sensitivity analysis after removal of SNPs identified by Phenoscanner						
Susceptibility	10	0.97 (0.77, 1.23)	0.798	0.083	0.004 (-0.032, 0.040)	0.834
Hospitalization	10	1.09 (0.68, 1.75)	0.714	0.010	0.014 (-0.059, 0.088)	0.713
Severe disease	10	0.91 (0.54, 1.55)	0.730	0.095	0.072 (-0.003, 0.146)	0.097

Table 2: MR results. SNP: single nucleotide polymorphism. nSNPs: number of SNPs retained for this analysis. IVW: inverse-weighted variance method. CI: confidence interval. Confidence intervals were obtained using Normal approximations, explaining minor discrepancies with p-values close to the alpha=5% statistical significance threshold.

Figure 1: Odds ratio point estimates and 95% confidence intervals for a one standard deviation increase in 25OHD levels (on the log scale) on Covid-19 susceptibility and severity. Restricted to 25-OHD Genes: analysis restricted to SNPs near the 4 genes involved in known vitamin D metabolic pathways. Phenoscanner Filtered: analysis restricted to the 4 genes above, and with removal of SNPs identified to have other associations in Phenoscanner.
