Abstract

Objective: In this umbrella systematic review, we screen existing reviews on using artificial intelligence (AI) techniques to diagnose COVID-19 in patients of any age and sex (both hospitalised and ambulatory) using medical images and assess their methodological quality.

Methods: We searched seven databases (MEDLINE, EMBASE, Web of Science, Scopus, dblp, Cochrane Library, IEEE Xplore) and two preprint services (arXiv, OSF Preprints) up to September 1, 2020. Eligible studies were identified as reviews or surveys where any metric of classification of detection of COVID-19 using AI was provided. Two independent reviewers did all steps of identification of records (titles and abstracts screening, full texts assessment, essential data extraction, and quality assessment). Any discrepancies were resolved by discussion. We qualitatively analyse methodological credibility of the reviews using AMSTAR 2 and evaluate reporting using PRISMA-DTA tools, leaving quantitative analysis for further publications.

Results: We included 22 reviews out of 725 records covering 165 primary studies. This review covers 416,254 participants in total, including 50,022 diagnosed with COVID-19. The methodological quality of all eligible studies was rated as critically low. 91% of papers had significant flaws in reporting quality. More than half of the reviews did not comment on the results of previously published reviews at all. Almost three fourth of the studies included less than 10% of available studies.

Discussion: In this umbrella review, we focus on the descriptive summary of included papers. Much wasting time and resources could be avoided if referring to previous reviews and following methodological guidelines. Due to the low credibility of evidence and flawed reporting, any recommendation about automated COVID-19 clinical diagnosis from medical images using AI at this point cannot be provided.

Funding: PO was supported by NIH grant AI116794 (the funding body had no role in the design, in any stage of the review, or in writing the manuscript); PJ and DS did not receive any funding.

Registration: The protocol of this review was registered on the OSF platform [1].

1 Introduction

In early December 2019, a new coronavirus epidemic was identified in Wuhan, Hubei Province, China [2]. Coronavirus disease 2019 (COVID-19) is a viral infection spread by direct contact with people with the illness (from droplets generated by sneezing and coughing), or indirectly [3]. It is caused by Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2). As of May 3, 2021, over 152 million people have been diagnosed with COVID-19, with nearly 3.2 million associated deaths¹. Two first waves of COVID-19 affected many societies, as well as scientific organisations [4–7]. On January 30, 2020, the World Health Organisation (WHO) issued a public health emergency of international concern (PHEIC) associated with COVID-19, and declared the state of a pandemic on March 11, 2020 [8].

Disease manifestation is variable, with some infected people remaining asymptomatic (even up to 10% [9]) and others suffering from mild (including fever, cough and aches) to severe (involving lethargy with dyspnea and increased respiratory rate) and critical manifestations (requiring mechanical ventilation). It may lead to serious neurological, musculoskeletal, or cerebrovascular disorders or may even progress to a life-threatening respiratory syndrome in some patients [10, 11]. Moreover, in 80% of patients, COVID-19 leaves one or more long-lasting symptoms, with fatigue, headaches, attentional difficulties, anosmia, memory loss manifested the most frequently [12]. Wide-ranging longer-term morbidity has also been described in the absence of a severe initial illness [13].

With limited access to healthcare and qualified personnel due to pandemic, an early diagnosis of COVID-19 is essential in preventing transmission of the virus. Identification of infected allows for better management of the pandemic (e.g. isolation, quarantine, hospital admission or admission to the intensive care unit) [14].

¹See: <https://covid19.who.int/>. Accessed on May 3, 2021.

Understanding the accuracy of tests and diagnostic features seems essential to develop effective screening and management methods [15].

There are many diagnostic evaluation challenges due to the COVID-19 pandemic. The primary method for diagnosing COVID-19 is Nucleic Acid Amplification Tests (NAATs) that use different methods to amplify nucleic acids and detect the virus, e.g. strand displacement amplification, reverse transcription-polymerase chain reaction (RT-PCR), or transcription-mediated amplification [16]. It utilises respiratory tract samples (mainly from the nasopharynx or oropharynx). However, some guidelines recommend nasal swabs [16], and some evidence suggests lower respiratory samples, such as sputum, may have higher sensitivity [17]. Serological tests are being used for detecting antibodies to SARS-CoV-2 for confirmation of past infection [16]. Nevertheless, there are concerns regarding the evidence for their accuracy and value in specific populations and clinical situations [18]. Additionally, rapid antigen and molecular-based tests are also available, but their diagnostic effectiveness is still unclear [16].

At the same time, the role of medical imaging in COVID-19 patients is emerging. It provides fast and sound insight into the lungs status and thus is used in emergency departments [15]. From the pandemic onset, chest radiography (X-Ray) has been used as a helpful tool for COVID-19 diagnosis [19]. However, diagnosing based on X-Ray is challenging, as even a normal chest radiography does not confirm that the patient has COVID-19, especially when it is an early stage [20].

A computed tomography (CT) has been able to discover COVID-19 abnormalities with sensitivity exceeding 97%. Some evidence suggests it helps to detect COVID-19 earlier than manifested by the positive RT-PCR test [21, 22]. CT as a diagnostic tool for COVID-19 was reported to have over 90% sensitivity, but only from 25% to 83% of specificity for symptomatic patients [23]. Positive COVID-19 diagnosis using CT has not been sufficient to determine the severity and the outcome of the disease [21].

With the increasing role of medical imaging as a diagnostic tool for COVID-19, a question arises if and to which extent automated tools can be included in clinical diagnosis. Up to this day, artificial intelligence (AI), or more specifically, deep learning (DL), have started to play an increasingly vital role in medicine [24]. In some recent studies and clinical trials, AI has been demonstrated to match or even exceed the performance of expert radiologists, which could potentially offer expedited and less expensive diagnostics [25–30]. A recent study and meta-analysis by Li et al. [31] with 31,587 identified and 82 included studies shows deep learning is capable of slightly outperforming health care professionals in detecting diseases from medical images with a pooled sensitivity of 87% (vs 86% of health care professionals) and pooled specificity of 93% (vs 91% respectively). Overlapping confidence intervals suggest that there is no statistically significant difference in performance between AI and human.

Since the onset of the pandemic, multiple initiatives have been taken in order to share data and knowledge on COVID-19 between researchers [32], just to mention COVID-19 Open Research Dataset Challenge (CORD-19) database with over 400,000 articles (over 150,000 with full text) as of May 3, 2021 on COVID-19 and related diseases ready for data mining on a popular Kaggle server for data science² or Global literature on coronavirus disease³ led by World Health Organisation.

The surge of primary studies is followed by the rise of the reviews summarising previous work. However, the emergency of the COVID-19 topic seemed to have led to increase overlap and degradation of the quality of the research [33].

This umbrella systematic review aims to screen existing reviews on using artificial intelligence (AI) techniques to diagnose COVID-19 in patients of any age and sex (both hospitalised and ambulatory) using medical images and assess their methodological quality. We provide evidence that reliable systematic reviews regarding this topic are in great need. The extended quantitative analyses, as well as in-depth credibility exploration, will be published separately.

2 Methods

2.1 Eligibility criteria, Protocol

We focused on any review (systematic or not) that includes primary studies utilising AI methods with medical imaging results to diagnose COVID-19. We were particularly interested in the performance of such classification systems, e.g. accuracy, sensitivity, specificity. We excluded these primary studies that used reference standards other than assay types (NAATs, antigen tests, and antibody tests) from nasopharyngeal or oropharyngeal swab samples, nasal aspirate, nasal wash or saliva, sputum or tracheal aspirate, or bronchoalveolar lavage (BAL) [16, 34]. Additionally, due to overlapping and double referencing of the post-conferencing articles (particular chapters), we excluded entire proceeding and post-conference books as they contain little information about the topics (presented in chapters) *per se*. However, we did not exclude reviews (chapters) as they were still present in our search. The protocol of this review was published [35] and registered [1] on the OSF platform.

2.2 Search methods

In order to determine whether there are any eligible papers, we conducted a pre-search in the middle of August 2020 via Google Scholar by browsing. We searched seven article databases (MEDLINE, EMBASE, Web of Science, Scopus, dblp, Cochrane Library, IEEE Xplore) and two preprint databases (arXiv, OSF Preprints) from inception to 01 September 2020 using predefined search strategies. We checked included preprints for peer-reviewed version before extraction phase.

In developing the search strategy for MEDLINE, we combined the Medical Subject Headings (MeSH) and full-text words. They concerned artificial intelligence, diagnostics, imaging and COVID-19. We adapted

²See: <https://www.kaggle.com/allen-institute-for-ai/CORD-19-research-challenge>. Accessed on May 3, 2021.

³See: <https://search.bvsalud.org/global-literature-on-novel-coronavirus-2019-ncov/>. Accessed on May 3, 2021.

the MEDLINE strategy for other sources searched. In Appendix A, we present used strategies. No date or language restrictions were adopted. Additionally, we searched references of included studies for references.

2.3 Definitions

We defined the terms used in our eligibility criteria below. *Review* refers to a paper identified by authors as a review or a survey. *AI* refers to computer programs that can perform tasks as intelligent beings [36]. *COVID-19* refers to a disease caused by the SARS-CoV-2 virus [37]. *Imaging* refers to individuals medical imaging results (e.g., CT scans, X-rays, ultrasound images) [38, 39]. *Diagnosis* refers to the identification of an illness (here: COVID-19)⁴. *Performance metrics* refers to evaluating machine learning algorithms. These measures are utilised to juxtapose observed data (actual labels) with the predictions of the model [40].

2.4 Data collection

Using Endnote (Claritive Analytics ®) and Rayyan [41], we checked identified references for duplicates. PJ, DS, PO independently screened the remaining references using the latter application. Subsequently, the reviewers (PJ, DS, PO) assessed the full texts for meeting the inclusion criteria separately. We pre-specified an extraction form, and PJ and DS collected all necessary data independently. As specified in the protocol [1], we gathered information about authors, funding, population, models, outcomes – AI methods performance, and additional analyses, e.g. interpretability.

To improve the understanding of the criteria among the reviewers, we carried out pilot exercises before each phase of this umbrella review (screening of titles and abstracts, full texts assessment, data extraction, credibility assessment). We achieved consensus via discussion if any conflicts (at each step of identification) occurred.

2.5 Quality assessment

The evaluation was conducted independently by PJ and DS. All discrepancies were resolved by discussion.

We assessed the methodological credibility using an extended version of the QASR tool [42] and AMSTAR 2 [43] with critical items (2, 4, 7, 9, 11, 13, and 15). In this study, we present only results from the latter instrument since the comprehensive assessment of included reviews will be published separately. The general quality across the study was assessed as critically low when at least one item in a critical domain was evaluated as a flaw.

Additionally, we assessed the quality of reporting in included studies using the PRISMA-DTA Checklist [44]. We rated each module on the 3-item scale: 0 (no with no compliance), 0.5 (partial yes with fragmentary compliance), 1 (yes with total compliance). Next, the results were summed, and the overall score was then assigned. Applying the Li et al. method [45], we differentiated the quality of reporting as follows:

- major flaws when the final score was ≤ 15.0 ,
- minor flaws when the final score was between 15.5 and 21.0,
- minimal flaws when the final score was ≥ 21.5 .

2.6 Analyses

In this umbrella review, we focus on the descriptive summary of included papers regarding quality and reporting on population, models, and interpretability. To identify a scale of wasting of time and resources, we also extracted bibliometric data about publishing dates (availability), sending to the editors (first and last version), and acceptance. Moreover, we checked how much evidence overlap across included reviews. In all tables and figures, included reviews are sorted by date of the last received version of the article; if it was not available, we used acceptance or published date (available online), whichever first occurred.

The quantitative analysis and following additional analyses will be published separately, as well as extended credibility evaluation. Thus, we do not present a subgroup analysis and investigation of heterogeneity or sensitivity analysis in this paper.

3 Results

3.1 Included studies

After removing duplicates, we screened 725 studies, of which 33 were read in the form of full texts. In total, we included 22 reviews [46–67] for qualitative synthesis. Our reporting is consistent with Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines [68]. The full study flow is presented in Figure 1.

The bibliometric characteristics of included studies are shown in Table 1 and in Appendix D. The lists of included and excluded studies (with reasons) are presented in Appendices B and C, respectively. None of the studies included meta-analysis, but one summarised the results as an average without weights [60].

There were 399,374 participants in total in analysed studies. 46,753 of them suffered from COVID-19 (12%). None of the reviews provided information about ethnicity, smoking, and comorbidities (diabetes mellitus, cardiovascular disorders, obesity, respiratory diseases, autoimmuneological, or others). Only one review [57] reported on age and gender proportion. Table 2 presents detailed features.

3.2 Quality of included studies

The general quality of all included studies is critically low (see Figure 2). 6 [51–53,55,57,66] reviews provided full information about sources of funding and conflict of interest. It was the most satisfied item. None of the studies provided a list of excluded papers, explanation of eligible study design and sources of funding in included studies.

Figure 2: Quality graph: our judgements on each AMSTAR 2 item presented as the percentage of all included studies.

A heatmap with all authors’ judgements regarding AMMSTAR 2 items per specific review can be found in Appendix H. In Appendix I, we also included summarised results per specific review.

Due to the lack of quantitative synthesis in the included reviews, we decided to lower the cut-offs for the overall reporting quality assessment. The thresholds were changed as follows: ≤ 14.5 , 14.5-21.0, and ≥ 21.0 for major, minor or minimal flaws, respectively.

Major flaws are present among 20 of included papers. All the rest [57,66] reviews contain minor drawbacks (see Figure 3 and Appendices F and G). The most affected domains were these concerning additional analyses both in terms of methods and results (all reviews). Similarly, a summary of evidence was not reported in any review.

Figure 3: Quality of reporting graph: our judgements about each PRISMA-DTA item presented as averages (with 95% confidence intervals) across all included studies.

Furthermore, 12 of included papers ([46, 48, 51–53, 55, 57–60, 66, 67]) reported fully on funding. Additionally, 11 reviews ([46, 47, 49, 54, 55, 58, 59, 61, 62, 65, 66]) and 8 reviews ([46, 48, 49, 54–56, 60, 66]) described rationale and objectives in the introduction adequately. These were the most satisfied domains.

The mean overall score of reporting quality across the included reviews equals 6.23 (1.5-17.5). Across all items and studies, the most frequent score was 0 (*no*) with 67%. 19% of the times, we assessed the items as 0.5 (*partially yes*).

A heatmap with all authors’ judgements regarding PRISMA-DTA items per specific review can be found in Appendix F. In Appendix G, we also included summarised results per specific review.

3.3 Analyses

The included studies were published or available online without peer-reviewing from April 11, 2020 to October 12 2020 (see Appendix B). In Figure 4, we presented a cumulative (from April to September 2020) chart of all 165 primary studies included in discussed reviews. The number of included interesting studies (related to our research question) in selected reviews ranged from 1 [51–53] to 106 [62]. Additionally, we present the percentage of unique articles per review. Unique means that such a study was introduced by a particular review.

50% of all primary studies (the half-saturation constant) were included at least once before the end of July. However, the same number of papers was available for inclusion three months earlier.

Figure 4: The cumulative chart of included, available, and unique primary papers among included reviews.

Investigating the citations between the reviews, we considered two different scenarios: citing only published reviews and citing both published and preprint versions. In the first case, 0.81 (0-4) reviews were cross-cited. While in the second condition, 1.1 (0-7) published papers or preprints were quoted by the authors of the subsequent reviews. Notably, 12 (55%) of reviews did not cite any previous reviews at all.

In the next step, we analysed how extensive was the search performed by the authors of the reviews, i.e. to which extent the authors identified the primary studies available up to reference date. By a reference date, we considered the day that the review was either received, or accepted by the editors, or published (See Appendix B). The mean percentage of the primary studies covered was 14%, (1-64). Relaxing this condition to the date the last cited paper included in the review was available, the mean percentage of covered studies increased to 24% (1-65). For the full details, see Table 10 (Appendix E).

14% of studies did not include any new paper into consideration. The mean unique primary studies included in particular review was 7.24 (0-45).

4 Discussion

Since the emergence of COVID-19 pandemic, over 120,000 related papers (and growing) were published, according to the LitCovid tracking website [69] and NIH OPA iSearch COVID-19 Portfolio⁵. The urgency of reporting novel findings and high pressure to publish COVID-19 related research quickly has been reported to lead to exceptions to high standards of quality [70, 71], lowering methodological credibility of some of the articles [72], or even accepting papers with many analytical errors [73]. Even the quality of the papers published in the three of the most prestigious journals in the field of healthcare: the New England Journal of Medicine, The Lancet, and the Journal of the American Medical Association, was reported to be below their average [74]. Lowered methodological credibility of COVID-19 research papers was also observed in 686 COVID-19 screened articles extracted by Jung et al. from 14,787 COVID-19 papers [75]. An analysis of reviews on COVID-19 by Yu et al. [76] also showed their unsatisfactory credibility. Out of 17 available reviews published before September 1, 2020, 5 (29%) were found to be of low and the remaining 12 (71%) of critically low quality. This is also in line with Li et al. [31] who assessed 63 systematic reviews (25%) to have low and 150 (62%) to have critically low quality. The authors also evaluated reporting using PRISMA [77], and the median score was 14 (10-18). This adds on top of generally low quality of reporting of DL performance from medical images, with high risk of bias present in 58 out of 81 of the existing studies (72%) [78].

Similar conclusions come from our study – we report that the quality of the included reviews was critically low. There were several critical domains that all the reviews failed to meet (selection criteria, list of excluded

⁵See: <https://icite.od.nih.gov/covid19/search/>. Accessed on May 3, 2021.

studies, discussing heterogeneity). Poor quality is not related only to COVID-19 articles and AI. Still, it occurs in many fields like bariatric surgery with 99% critically low articles [79], psychology with 95% [80] or methodological where 53 out of 63 publications were critically low of quality [81]. What is more, the reporting was also poor. Three PRISMA-DTA domains were fully flawed in all reviews (additional analyses in methods and results descriptions, summary of evidence and discussion). Only in one review [64], the authors provided description of methods used for synthesis partially. Although the included studies focused on diagnostics, the authors hardly report any accuracy measure and explicit description of the extraction process.

In the reviewed works, we found multiple disagreements on the numbers extracted from the primary studies. We found no data on many population features because of missing information and misleading or unclear statements, e.g. providing different information in text and figures and tables. Lack of scientific precision, e.g. reporting the *number of cases*, understood either as X-Ray images, or patients, without any discussion if the cases were symptomatic or not. Inconsistencies were also noticed in reporting of DL architecture. For instance, the following names were used across multiple studies: *ResNet-18*, *ResNet18*, *resnet-18*, *18-layer ResNet*. In some of the papers, the architecture was not reported at all.

Some level of discrepancy was also observed in extracting the measurements of AI models performance. For example, the diagnostic effectiveness metrics from primary studies were either not reported or incorrectly reported by multiple studies. Such negligence may lead to further replicating the errors by subsequent studies and should be corrected before releasing the paper, or soon after in an updated version or erratum.

The amount of waste and poor biomedical research quality is staggering [70,82]. Papers that do not bring any additional knowledge to the field can be deemed redundant in line with multiple papers and International Committee of Medical Journal Editors (ICMJE) guidelines [83–86].

Many of the reviews included in this paper did not contribute to strengthening the evidence on using AI in diagnosing COVID-19 from medical imaging. Those works have not even identified and correctly cited preexisting studies, which is deemed the essence of any research. Some of the potential explanations are that multiple similar studies might have been initiated around the same time and prolonged review times impacted their content. Alternatively, the papers were too broadly focused and have not actually touched on application of AI to medical imaging. As the research questions might have not been strict, the reviews might have been focused on vast areas, e.g. using AI in the battle of COVID-19.

The low credibility of evidence, flawed reporting (e.g. on population characteristics), could be associated with lack of knowledge of reporting standards, clinical practice, or misunderstandings regarding AI techniques.

Proper reporting of deep learning performance from primary research studies is challenging. Naude [32] has pointed out some of the major concerns regarding adoption of AI in COVID-19 research, including data availability, sufficient quality of the data (lack of noise and outliers) as well as privacy protection. Still many studies do not share the source code as open source, which highly limits reproducibility of their findings [87,88].

4.1 Study Strengths & Limitations

Our umbrella review has the following strengths. First, the search strategy was comprehensive based on adequate inclusion criteria related to research question, and spanned across a wide selection of existing data sources: papers and preprints. This selection was further expanded by searching the references of included papers to identify new works. Noteworthy, the searches were not limited in terms of format or language. The process of our review was rigorous as the study was proceeded by the publication of protocol. We used the most up-to-date and applicable tools to assess credibility and quality of reporting – AMSTAR 2 and PRISMA with extension for DTA, respectively. Nevertheless, these instruments have been designed for reviews in the fields of medicine and health sciences, where the formulation of the research question is structured, the methodology is validated and the quantitative synthesis of results is more popular. There are also other limitations associated with this study. Although our exhaustive and sensitive search covered multiple aspects, some studies might have still been missed. We did not search for Chinese data sources that could include many valuable papers. Secondly, it must be noted that the vast majority of the included studies focused on a broader context than purely diagnosing COVID-19 from medical images.

In this study, we have investigated wasting among the reviews. We based on the date of publishing of the last included primary study in particular review. This approach aims at assessing the depth of the search performed by the authors. We assumed that if the authors included a given study, they should have had the required knowledge about all the studies that appeared prior that date. This approach relaxes the strict requirement to include all the studies that appeared before the review was published and seems to more objectively measure the quality of the search. Due to the lack of validated method, we based this approach on intuition.

This study does not include quantitative analysis and extended credibility evaluation, as this is planned to be addressed in the follow-up papers. Thus, we also do not present a subgroup analysis and investigation of heterogeneity nor sensitivity analysis.

5 Conclusions

The COVID-19 research is quickly moving forward, each day hundreds of new papers are published. As AI starts to play increasingly important role in clinical practice [89,90], it is crucial to properly evaluate its performance using well established standards.

In this paper, we synthesised and assessed the quality of the 22 reviews that mention using AI on COVID-19 medical images. We reviewed them and critically assessed their quality using well established instruments from PRISMA-DTA [44] and AMSTAR 2 [43].

The overall conclusion from this study is that we still need high quality evidence to prove the effectiveness of AI in detecting COVID-19 from medical images. The recommendation on using AI to detect COVID-19 in medical images can not be provided until more credible studies are presented, and the certainty of evidence becomes evaluated using well established techniques.

In order to accomplish this, we urge the authors of the systematic reviews to use PRISMA and AMSTAR 2, and the authors of primary studies to adapt the *Checklist for Artificial Intelligence in Medical Imaging (CLAIM)* – a new standard for transparency and reproducibility of the research [91].

It is high time to adapt best practices and improve the quality of the research, as well as to apply higher scrutiny in filtering out nonconstructive contributions.

Authors contributions

We followed CRediT (Contributor Roles Taxonomy) to report on authors contributions.

1. Paweł Jemioło (PJ): Conceptualisation, Validation, Formal analysis, Investigation, Data Curation, Writing – Original Draft, Writing – Review & Editing, Visualisation, Project administration.
2. Dawid Storman (DS): Conceptualisation, Methodology, Validation, Formal analysis, Investigation, Writing – Original Draft, Writing – Review & Editing, Visualisation.
3. Patryk Orzechowski (PO): Conceptualisation, Investigation, Software, Visualisation, Writing – Original Draft, Writing – Review & Editing.

Conflict of Interest

Authors declare that they have no conflict of interest.

Funding Sources

PO was supported by NIH grant AI116794 (the funding body had no role in the design, in any stage of the review, or in writing the manuscript); PJ and DS did not receive any funding.

Acknowledgement

The authors would like to thank Prof. Jason H. Moore from the University of Pennsylvania for his kind support and useful suggestions.

Data and Code Availability

Full extraction forms and code used in this research can be accessed via contact with corresponding author.
