46

Abstract

47

48 *Objective:* To characterize the evolution of healthcare workers' mental health status over the
49 1-year period following the initial COVID-19 pandemic outbreak and to examine baseline
50 characteristics associated with resolution or persistence of mental health problems over time.

51 *Methods:* We conducted an 8-month follow-up cohort study. Eligible participants were
52 healthcare workers working in Spain. Baseline data were collected during the initial pandemic
53 outbreak. Survey-based self-reported measures included COVID-19-related exposures,
54 sociodemographic characteristics, and three mental health outcomes (psychological distress,
55 depression symptoms, and posttraumatic stress disorder symptoms). We examined three
56 longitudinal trajectories in mental health outcomes between baseline and follow-up
57 assessments (namely *asymptomatic/stable*, *recovering*, and *persistently*
58 *symptomatic/worsening*).

59 *Results:* We recruited 1,807 participants. Between baseline and follow-up assessments, the
60 proportion of respondents screening positive for psychological distress and probable
61 depression decreased, respectively, from 74% to 56% and from 28% to 21%. Two-thirds
62 remained asymptomatic/stable in terms of depression symptoms and 56% remained
63 symptomatic or worsened over time in terms of psychological distress.

64 *Conclusions:* Poor mental health outcomes among healthcare workers persisted over time.
65 Occupational programs and mental health strategies should be put in place.

66

68 cohort

COVID-19 impact on healthcare workers

69 The COVID-19 pandemic outbreak has had substantial mental health impact on healthcare
70 workers (HCWs), largely due to increases in healthcare capacity requirements driving job
71 redeployments and extended working hours in combination with very high risk of contagion
72 and death. Estimates from cross-sectional studies conducted during the initial pandemic
73 outbreak suggest that between 25 and 50% of HCWs may have experienced clinically
74 significant symptoms of anxiety or depression (1–7) and posttraumatic stress (1,3,7).

75
76 The extent to which the deleterious mental health effects brought about by the initial pandemic
77 outbreak may have subsequently led to negative mid- and long-term mental health outcomes
78 among HCWs. However, these remain largely unexplored, despite important public health and
79 clinical implications (8). Initially, it seemed plausible that a large proportion of the burden of
80 mental health symptoms initially reported by HCWs would eventually resolve, either
81 following cessation of exposure to the acute stressor or after adequate targeted interventions
82 (e.g., self-care and low-intensity psychotherapeutic interventions). Nevertheless, because the
83 initial pandemic outbreak has been followed by a series of ongoing subsequent pandemic
84 waves that continue to strain health systems across the globe, there is a generalized concern
85 that a substantial proportion of HCWs may be experiencing persistent mental health problems.
86 According to the World Health Organization, reducing the long-term mental health impact of
87 the pandemic on HCWs is considered a major clinical and public health priority. Estimating
88 the mid- and long-term mental health impact of the COVID-19 pandemic among HCWs is
89 paramount for occupational and mental healthcare planning purposes. In addition, identifying
90 risk and protective factors for persistence of clinically significant mental health burden can
91 help improve implementation of evidence-based detection and treatment strategies.
92 Notwithstanding, evidence examining prevalence and predictors of persistence of mental
93 health symptoms among HCWs from longitudinal cohort studies is scarce (9–12).

94
95 Here we used a large sample of HCWs during the one-year period following the initial
96 pandemic outbreak in one of the largest COVID-19 hotspots globally to (1) characterize the
97 evolution of HCWs' mental health status over the year following the initial pandemic
98 outbreak, and (2) examine baseline sociodemographic and clinical characteristics associated
99 with resolution or persistence of mental health problems over time.

100

101

Methods

102

Study design, setting, and participants

103

104

105 We conducted a prospective cohort study in Spain as part of an ongoing longitudinal multi-
106 national study (<https://mentalnet.ci/en/home/>). We collected data through an online survey at
107 two timepoints. Baseline assessments were performed from April 24th to June 22nd, 2020
108 (during the initial pandemic outbreak in Spain). Follow-up assessments took place between
109 January 26th and March 8th, 2021, which in Spain coincided with the third pandemic wave and
110 with administration of COVID-19 vaccines for the majority of HCWs.

111

112 The study participants were HCWs aged 18 years and older, recruited from different
113 outpatient and inpatient healthcare facilities, with clinical and non-clinical duties, and not
114 necessarily involved in the direct care of COVID-19 patients. The sampling strategy was as
115 follows. During both the baseline and follow-up assessments, key stakeholders (e.g., hospital
116 managers, heads of worker unions) from healthcare facilities located in the study regions
117 (Andalusia, Madrid, and Murcia) forwarded the survey link to all HCWs. Participants were
118 also asked to forward the survey to peers in order to enhance response rates. In addition,
119 during the follow-up period, we sent email or telephone survey reminders to baseline
120 participants. Baseline assessments are described elsewhere (13). In this manuscript, we focus
121 on participants who were assessed at follow-up only and on participants assessed at follow-up
122 who had been assessed also during baseline procedures. We hereafter refer to these two
123 subgroups as *partial* and *full respondents*, respectively.

COVID-19 impact on healthcare workers

124

125 All procedures contributing to this work comply with the Helsinki Declaration of 1975, as
126 revised in 2013. It received approval from the Hospital La Paz Ethics Committee (Madrid,
127 Spain) and was ratified by the local ethics committees from the participating sites.

128

129 *Variables*

130

131 Baseline assessments included the following COVID-19-related exposures: direct involvement
132 in the care of COVID-19 patients (yes, no), adequate access to personal protective equipment,
133 fear of getting infected, and fear of infecting loved ones (all rated from 0 to 3).

134

135 Both baseline and follow-up assessments included the following sociodemographic and
136 mental health outcome variables.

137

138 *Sociodemographic variables:* Age in years, gender (male, female), educational level (primary,
139 secondary, or university studies), and type of job. We collapsed job types into the following
140 categories: physicians, nurses, health technicians (e.g., nurse, X-ray, and laboratory
141 technicians), ancillary workers (e.g., security staff, drivers, administrative staff, and cleaning
142 staff), other HCWs (e.g., clinical psychologists, physiotherapists, and biologists), and
143 residential support workers (e.g., from mental health assisted living facilities, nursing homes).

144

145 *Mental health outcomes:* Psychological stress, as measured by the Spanish version of the 12-
146 item General Health Questionnaire (14); and probable depression symptoms, as measured by
147 the Spanish version of the 9-item Patient Health Questionnaire (PHQ-9) (15). We used widely
148 accepted thresholds for detecting people screening positive for psychological distress (GHQ-
149 12 higher than 2 points) (16,17) and for depression (PHQ-9 score higher than 9 points) (18). In
150 addition, follow-up assessments also included posttraumatic stress disorder (PTSD)
151 symptoms, as measured by the Spanish 5-item version of the Primary Care PTSD Screen for
152 DSM-5 (PC-PTSD-5), where a total score higher than 2 points suggests probable PTSD (19).

153

154 Cronbach's alphas were 0.87 (95 percent CI: 0.86, 0.88) for the GHQ-12 total score; 0.89 (95
155 percent CI: 0.88, 0.89) for the PHQ-9 total score; and 0.70 (95 percent CI: 0.68, 0.72) for the
156 PC-PTSD-5. To control for region-level cumulative COVID-19 incidence, we calculated
157 region-specific 14-day cumulative incidence rates 2, 4, 6, and 8 weeks after the start of the
158 follow-up period and, as rates were stable over time, classified regions as "high" or "low"
159 incidence depending on whether average cumulative incidence over time points fell under or
160 over 750 cases per 100,000 based on visual examination of region-specific cumulative
161 incidence rates (**Supplementary Figures 1 and 2**).

162

163 *Statistical analyses*

164

165 First, we removed baseline respondents who provided informed consent but did not go on to
166 initiate the survey (n = 95). We reported categorical variables as frequencies and valid
167 percentages, and continuous and interval variables as either mean (standard deviation [SD]),
168 or median (interquartile range [IQR]). Descriptive statistics were calculated separately for full
169 and partial respondents.

170

171 Then, we used multivariable mixed-effects linear and binary logistic regression models to
172 explore the associations between baseline variables, including sociodemographic
173 characteristics (i.e., age, gender, and educational level) and COVID-19-related exposures (i.e.,
174 direct involvement in the care of COVID-19 patients, adequate access to personal protective
175 equipment, fear of getting infected, and fear of infecting loved ones), and follow-up mental
176 health outcomes (i.e., psychological distress, depression symptoms, and PTSD symptoms),
177 defined both as continuous questionnaire scores and dichotomous variables. We conducted
178 sensitivity analyses adjusted by baseline assessments of the follow-up outcome under

COVID-19 impact on healthcare workers

179 consideration. We used baseline GHQ-12 score for the model where follow-up PTSD was the
180 outcome, as we did not have estimates for the latter in the baseline assessment. The GHQ-12
181 score, an instrument that has good convergent validity with the PC-PTSD-5 and accurately
182 detects PTSD in primary care settings (20).

183

184 Next, we used baseline and follow-up mental health outcomes to categorize respondents into
185 three mental health trajectories, separately for psychological distress and for depression,
186 according to whether they screened negative at baseline and follow-up (*asymptomatic stable*),
187 positive at baseline and negative at follow-up (*recovering*), or positive or negative at baseline
188 and positive at follow-up (*persistently symptomatic/worsening*). For instance, if a respondent
189 screened negative in the GHQ-12 and positive in the PHQ-9 at baseline, and subsequently
190 screened positive in the GHQ-12 and negative in the PHQ-9 at follow-up, they would belong
191 to the *persistently symptomatic/worsening* trajectory for psychological distress and to the
192 *recovering* trajectory for depression. We selected these trajectory categories because of their
193 potential implications for clinical practice.

194

195 Finally, we explored the association between baseline exposures and longitudinal
196 psychological distress and depression trajectory membership, using multinomial regression
197 models where *asymptomatic stable* was considered the reference category. Baseline exposures
198 were age group, gender, educational level, direct involvement in the care of COVID-19
199 patients, adequate access to personal protective equipment (adequate vs. inadequate), fear of
200 getting infected (not or slightly afraid vs. considerably or extremely afraid), and fear of
201 infecting loved ones (not or slightly afraid vs. considerably or extremely afraid).

202

203 All models were adjusted by covariates to control for confounding based on prior causal
204 knowledge, using direct acyclic graphs and backdoor criteria (21). Region-level cumulative
205 incidence of COVID-19 was entered in all models as a fixed factor. We did not impute
206 missing data. All analyses were performed using packages *dplyr*, *gtsummary*, *flextable*,
207 *ggplot2*, *psych*, *multinom* of R Studio for Mac (Version 1.2.5042).

208

209 Results

210

211 Of 1,807 respondents who answered the survey at follow-up (between January 26th-March
212 25th, 2021), 1,471 (81.4%) completed the entire survey, with a median response time of 21
213 minutes. Most missing data pertained to the last section of the questionnaire, suggesting that
214 data missingness was driven by survey extension and hence largely random. Respondents who
215 did and did not complete the survey were comparable in terms of mean age (42 vs. 40 years,
216 respectively) and gender distribution (78% vs. 74% female, respectively). Response rates were
217 estimated across facilities and job types and ranged from 2.7% to 100% (see **Supplementary**
218 **Tables 1 and 2**).

219

220 There were 1,058 (59%) partial respondents (i.e., assessed only at follow-up) and 749 (41%)
221 full respondents (i.e., assessed at both baseline and follow-up). Of note, this indicates that we
222 retained 32% of the 2,370 original baseline respondents for follow-up assessments (see **Figure**
223 **1**). Sociodemographic characteristics of follow-up respondents, overall and divided into full
224 and partial respondents, are shown in **Table 1**. In short, full respondents were more frequently
225 female and more likely to have completed university studies than partial respondents. Also,
226 while most full respondents were physicians or nurses, partial respondents included a larger
227 proportion of residential support workers.

228

229 Overall, 56% of follow-up respondents screened positive for psychological distress, 21% for
230 probable depression, and 51% for PTSD. Psychological distress, probable depression, and
231 PTSD were more frequent among younger and female respondents, and respondents with
232 higher educational levels – with substantial heterogeneity across specific job types (see
233 **Supplementary Table 3**). Notably, follow-up mental health outcomes were comparable

234 between full and partial respondents, with similar mean (SD) GHQ-12 score (3.9 [3.5] vs. 3.8
235 [3.4], respectively), mean (SD) PHQ-9 score (6.3 [5.1] vs. 6.4 [3.4], respectively), proportion
236 of respondents screening positive for psychological distress (56% vs. 55%, respectively), and
237 proportion of respondents screening positive for probable depression (21% vs. 21%,
238 respectively).

239

240 Comparisons between baseline and follow-up mental health outcomes among full respondents
241 are shown in **Table 2**. The proportion of respondents screening positive for psychological
242 distress and probable depression decreased, respectively, from 74% to 56% and from 28% to
243 21%. **Figure 2** shows the distribution of trajectories of depression symptoms and
244 psychological distress over time, overall and across baseline covariates. Trajectories show
245 that, in terms of depression symptoms, 66% respondents remained asymptomatic/stable, 15%
246 recovered, and 19% remained symptomatic or worsened over time. In terms of psychological
247 distress, 18% respondents remained asymptomatic/stable, 26% recovered, and 56% remained
248 symptomatic or worsened over time. The distribution of trajectories was heterogeneous across
249 baseline covariates.

250

251 **Table 3** shows crude and adjusted estimates of the association between baseline exposures and
252 follow-up mental health outcome scores among full respondents. Overall, women had higher
253 scores (i.e., worse mental health) than men, and job-related factors such as direct involvement
254 in the care of COVID-19, inadequate access to protective equipment, or fear of infecting
255 oneself or loved ones were associated with higher negative mental health outcome scores -
256 especially for PTSD, and with higher odds of testing positive for psychological distress,
257 probable depression, and PTSD (see **Supplementary Table 4**). We repeated all models
258 including further adjustment by baseline mental health outcome scores: results did not change
259 substantially (see **Supplementary Tables 5 and 6**).

260

261 **Table 4** shows crude and adjusted associations between baseline exposures and trajectory
262 membership for psychological distress and probable depression. Women showed higher
263 symptom variability over time than men, as indicated by women's higher odds of belonging to
264 both the *recovering* and the *persistently symptomatic/worsening* categories for both
265 psychological distress and probable depression. In terms of psychological distress, reporting
266 inadequate access to personal protective equipment was associated with *persistently*
267 *symptomatic/worsening* category membership. In terms of probable depression, fear of
268 infecting loved ones was associated with *recovering* category membership.

269

270

Discussion

271

272 This study followed a cohort of HCWs from one of the earliest COVID-19 pandemic hotspots
273 over the one-year period after the initial pandemic outbreak. There was marked heterogeneity
274 across individuals in terms of variation in mental health outcomes over time. While we
275 detected general reductions in psychological distress (from 74 to 56%) and depression
276 symptoms (from 28 to 21%), the overall burden of poor mental health among HCWs remained
277 substantial 8 months after the pandemic onset (56% screened positive for psychological
278 distress, 21% for probable depression, and 51% for PTSD). Our analysis of mental health
279 outcome trajectories revealed that psychological distress and depression symptoms persisted
280 or worsened over time for 56% and 19% of respondents, respectively. We identified
281 prospective associations between certain baseline characteristics, such as being female,
282 reporting inadequate access to personal protective equipment, or being afraid of getting
283 infected and of infecting loved ones, and follow-up psychological distress, depression
284 symptoms, and PTSD symptoms. These results highlight the importance of adapting,
285 implementing, and scaling-up evidence-based public, occupational, and mental health
286 interventions for HCWs to prevent their mental health from further deteriorating during the
287 ongoing pandemic and its aftermath.

288

COVID-19 impact on healthcare workers

289 Early cross-sectional studies from high-incidence COVID-19 areas, such as the Chinese
290 region of Wuhan (22), Italy (3,5), or Spain (1), described the mental health toll taken by the
291 pandemic on HCWs' mental health, showing remarkable rates of psychological distress,
292 anxiety, depression, and PTSD symptoms. In our study sample, estimates of the point
293 prevalence of depression at baseline were similar than those found in Italy (25%) and Spain
294 (28%), probably due to similar sample characteristics and study settings. Likewise, our
295 baseline finding that three in four respondents were psychologically distressed is nearly
296 identical to that of Lai and colleagues in Wuhan at the beginning of the pandemic (late
297 January 2020). Additionally, a series of cross-sectional studies had already reported
298 associations between HCWs' characteristics, such as female gender, or inadequate access to
299 personal protective equipment and negative mental health outcomes (i.e., anxiety or
300 depression) (23–25). Our study found these associations to persist within a prospective cohort
301 design, lowering the risk of potential reverse causation bias and hence greatly enhancing
302 interpretability for decision-making.

303
304 Other prospective studies have sought to describe the evolution of HCWs' negative mental
305 health outcomes over time using a variety of outcomes and follow-up periods (9–12,25–28).
306 Somewhat in contrast to our results, López Steinmez and colleagues reported a slight increase
307 in psychological distress (from 40% to 46% point prevalence) between May and September,
308 2020, in a sample of 300 HCWs from Buenos Aires, Argentina. Differences in follow-up time
309 probably accounts for this between-study difference, as they may have captured the early
310 consequences of the initial pandemic outbreak while we conducted our assessments later,
311 when renovated reasons for optimism (e.g., vaccine development and roll-out) had already
312 started to emerge. Using a highly homogeneous sample of 200 nurses, Pinho and colleagues
313 reported stable trends in depression and decreasing trends in anxiety between April and
314 November, 2020. Differences in sample composition make their results hardly comparable to
315 our's. Other studies have either used much shorter follow-up periods (25,27,28) or reported
316 outcomes not comparable to our's, such as insomnia (26) or job stress (12). Our's is the first
317 prospective cohort analysis of risk factors for negative mental health outcomes among HCWs
318 to adjust all associations of interest for potential confounding due to area-level COVID-19
319 cumulative incidence, in addition to adjustment for individual-level confounding. Notably,
320 mounting evidence suggests higher rates of negative mental health outcomes among HCWs
321 from regions with higher incidence (29).

322
323 To our knowledge, only one study has described the trajectories of mental health problems
324 among HCWs during the COVID-19 pandemic (9). Using latent class modelling based on
325 scores on three mental health outcomes (depression, anxiety, and PTSD symptoms) between
326 May and September, 2020, they found four distinct trajectories which are remarkably similar
327 to ours in terms of interpretation and prevalence within the study sample: 19% respondents
328 belonged to their 'recovered' group (for 15% in our *recovering* group), 66% to their 'resilient'
329 group (for 66% in our *asymptomatic stable* group), and 7% and 8%, respectively, to their 'sub-
330 chronic' and 'delayed' groups (for 19% in our *symptomatic/worsening* group). These same
331 trajectories have been identified in studies using latent growth mixture modelling across many
332 different populations that have experienced adversity (30). Notably, this previous study did
333 not assess psychological distress. Accordingly, our surprisingly high rates of persistence or
334 worsening of psychological distress (56% of respondents) cannot be compared to other
335 studies. While this result does not lend itself to easy interpretation until subsequent follow-up
336 studies using the GHQ-12 emerge, it seems plausible that a substantial proportion of HCWs
337 may potentially benefit from implementation of programs to lower psychological distress.

338
339 In addition to confirming associations previously reported in cross-sectional reports, our
340 findings expand existing evidence in impactful ways for public health and clinical decision-
341 making. First, by including a heterogeneous sample of HCWs with and without clinical duties,
342 our study may serve to inform strategies aimed at non-clinical workers such as administrators
343 or cleaners – largely overlooked in most studies examining mental health outcomes among

COVID-19 impact on healthcare workers

344 HCWs during the COVID-19 pandemic. Second, our finding of scarce evidence of reliable
345 baseline predictors of mental health outcome trajectories over time suggests that all HCWs
346 should be offered easy-to-access mental health resources tailored to their needs (i.e., self-care
347 and low-intensity psychotherapeutic interventions), regardless of profile in terms of
348 sociodemographic characteristics and baseline clinical features.

349
350 Our study has limitations. First, we used a non-random sample that increases probability of
351 some degree of collider bias and hinders transportability of study results across settings. Also,
352 and in line with other multi-center studies (1,4), response rates varied significantly across sites
353 and facilities, and the possibility of self-selection bias cannot be ruled out. Nevertheless, the
354 baseline sociodemographic characteristics and mental health outcomes were however similar
355 to another Spanish study with a larger and somewhat more representative sample of HCWs (1)
356 and to other, similar European studies (2,3). Second, because of the use of observational data,
357 effect estimates are potentially subject to some degree of residual confounding. Notably,
358 substantial residual confounding is unlikely given that we included measures on all major
359 individual- and region-level confounders and that estimates from crude and adjusted
360 associations are roughly similar. Moreover, sensitivity analyses exploring differences between
361 subsamples (e.g., full vs. partial respondents) and adjusting for baseline measurements of
362 mental health outcomes obtained similar results, suggesting that our models were robust to
363 different model specifications. Third, two thirds of baseline respondents were lost to follow-
364 up. Dropout was independent from age, gender, and mental health outcomes at baseline, but
365 people lost to follow were slightly more concerned about getting the virus and infecting their
366 loved ones (data not shown). Fourth, limitations of self-reports for diagnostic screening are
367 widely known (31). In the context of HCWs' reactions to an initial pandemic outbreak,
368 available diagnostic thresholds might have misclassified early, adaptive reactions to acute
369 stressors as probable disorders (i.e., false positives). Notwithstanding, we used widely
370 accepted screening instruments with good psychometric properties validated worldwide. Last,
371 we calculated outcome trajectories based on information from two time points only. Future
372 steps will include ascertainment of mental health outcomes in subsequent follow-up
373 assessments and adoption of data-driven latent growth modelling approaches in addition to
374 previously established categories based on clinical implications.

375
376 This is the first study to describe the trajectories of change of a large sample of HCWs from an
377 early pandemic hotspot over a long follow-up period. Our results suggest preventative and
378 restorative strategies at various levels (i.e., public, occupational, and specialized mental
379 health), and outlines modifiable factors that might inform resource allocation, such as
380 provision of protective equipment or being in direct care of COVID-19 patients. Further
381 studies exploring the long-term impact of the pandemic among HCWs are warranted.
