Abstract:

Human coronavirus disease 2019 (COVID-19) due to severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) has multiple neurological consequences, but its long-term effect on brain health is still uncertain. The cerebrovascular consequences of COVID-19 may also affect brain health. Here we assess cerebrovascular health in 45 hospitalised patients using the resting state fluctuation amplitudes (RSFA) from functional magnetic resonance imaging, in relation to disease severity and in contrast with 42 controls. Widespread changes in frontoparietal RSFA were related to the severity of the acute COVID-19 episode, as indexed by COVID-19 WHO Progression Scale, inflammatory and coagulatory biomarkers. This relationship was not explained by chronic cardiorespiratory dysfunction, age, or sex. Exploratory analysis suggests that the level of cerebrovascular dysfunction is associated with cognitive, mental, and physical health at follow-up. The principal findings were consistent across univariate and multivariate approaches. The results indicate chronic cerebrovascular impairment following severe acute COVID-19, with the potential for long-term consequences on cognitive function and mental wellbeing.

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) causes human coronavirus disease 2019 (COVID-19) with multi-system effects that include neurological, vascular and neurovascular injury. Acute neurological sequelae are common, ranging from mild dizziness, headaches and anosmia to severe encephalitis, stroke and delirium (Chen et al., 2020; Hensley et al., 2021; Paterson et al., 2020; Zubair et al., 2020). These sequelae may arise from systemic physiological insults (e.g. hypoxia, hypotension, dysautonomia), coagulation dysfunction, large vessel occlusion, arterial stiffness, impaired vasoreactivity, neurotropic infection, parenchymal haemorrhage, or autoimmune responses against diverse antigens (Chen et al., 2020; Marcic et al., 2021; Mohkhedkar et al., 2021; Schnaubelt et al., 2021). Acute COVID-19 has also been associated with microvascular injury from vasculitis or endothelialitis (Becker, 2020; McGonagle et al., 2021), with endotheliopathy (Kakarla et al., 2021), vasogenic oedema and microthrombosis in the acute phase (Iba et al., 2020; Levi et al., 2020) and hypoperfusion in subacute phase (Hosp et al., 2021). While this acute pathophysiology is detectable using neuroimaging (Hanafi et al., 2020; Lersy et al., 2021; Newcombe

16 et al., 2020), the persistence and effects of cerebrovascular dysfunction over the medium- and long-
17 term remain unknown.

18

19 An important aspect of cerebrovascular function is the capacity of cerebral vessels to
20 constrict or dilate in response to physiological conditions such as alterations in carbon dioxide (CO₂)
21 and oxygen tension. This cerebrovascular reactivity (Willie et al., 2014) regulates regional blood flow
22 via pH-dependent modulation of vascular smooth muscle tone (Ainslie et al., 2005; Jensen et al.,
23 1988; Lambertsen et al., 1961; Lassen, 1968), but is compromised by arterial stiffness, compromised
24 endothelial function (Brandes et al., 2005), or disorders including hypertension, traumatic brain injury
25 and dementia. Poor cerebrovascular reactivity may also increase the risk of neurodegeneration (Gao
26 et al., 2013).

27

28 We therefore assessed the impact of COVID-19 on chronic cerebrovascular reactivity after
29 hospitalisation. We use a well-established non-invasive imaging method, exploiting naturally
30 occurring fluctuations in arterial CO₂ induced by variations in cardiac and respiratory cycles, which
31 moderate the blood oxygenation level-dependent (BOLD) signal underlying functional magnetic
32 resonance imaging (Birn et al., 2006; Glover et al., 2007). The BOLD signal variability at rest, known as
33 resting state fluctuation amplitudes (RSFA) is a safe, scalable and robust alternative to the gold
34 standard approaches (Kannurpatti and Biswal, 2008; Tsvetanov et al., 2020c, 2015). It is easier and
35 safer to apply in clinical cohorts than experimental hypercapnia, breath-holding and drug
36 interventions (Keyeux et al., 1995; Rostrup et al., 1996, 1994; Wagerle and Mishra, 1988). RSFA is
37 sensitive to cerebrovascular and cardiovascular differences in ageing (Garrett et al., 2017; Tsvetanov
38 et al., 2020b, 2015), small vessel disease (Makedonov et al., 2013), stroke (Nair et al., 2017; Raut et
39 al., 2016), Alzheimer's disease (Makedonov et al., 2016; Millar et al., 2020a), cognitive performance
40 (Liu et al., 2021; Millar et al., 2021, 2020b) and the presence of brain tumours (Agarwal et al., 2019,
41 2017).

42 We report on the chronic effect of COVID-19 on RSFA as a marker of cerebral microvascular
43 function, in relation to acute severity. Exploratory analyses examine the relationship to normative
44 regional variations in neurotransmitters/receptors, brain energy consumption and cell-type
45 distributions. Acute disease severity was quantified by the COVID-19 WHO Progression Scale and
46 blood biomarkers in patients hospitalised for COVID-19. We predicted that acute COVID-19 changes
47 regional RSFA at follow up, in proportion to acute disease severity, over and above the effects of
48 residual systemic cardiorespiratory impairment.

49 2. Methods

50

51 2.1. Participants

52 Patients were recruited through the NIHR COVID-19 BioResource, which received ethical
53 approval from East of England - Cambridge Central Research Ethics Committee (REC 17/EE/0025), and
54 provided written informed consent. Eligibility was based on admission to Addenbrookes Hospital with
55 COVID-19 between 10th March 2020 and 31st July 2020, aged 18 years or older, survived the acute
56 illness, and attended for a follow up visit, and no contradictions to MRI. 489 patients were potentially
57 eligible. Clinical data were obtained from inpatient electronic medical records, and from
58 cardiorespiratory and neurological assessment at follow-up clinical and research visits at least 6
59 weeks following symptom onset. 45 patients consented to participate, with clinical, structural and
60 functional resting state functional magnetic resonance imaging (fMRI) data of appropriate quality (see
61 below). Age and sex matched controls were scanned with the same sequences, with data pooled over
62 sequential cohorts to match demographics (Cambridgeshire Research Ethics Committee 97/290 and
63 REC 17/EE/0025, and Norfolk EE/0395 and a protocol approved by the Human Biology Ethics
64 Committee of the Council of the School of Biological Sciences, University of Cambridge). The study
65 and their processing pipelines are summarised in SI Figure 1.

66

67

68 2.2. Inpatient data: COVID-19 severity

69 The WHO COVID-19 11-point Progression scale was used to provide a measure of disease
70 severity with scores from 0 (non-infected) to 10 (dead) (see Figure 1 in Marshall et al., 2020). We also
71 used blood biomarkers previously associated with COVID-19 severity including the most extreme
72 values during hospitalisation on haematological (lowest platelets) (Wool and Miller, 2021),
73 inflammatory (C-reactive protein, CRP, serum ferritin) (Luan et al., 2021), immunological (interleukin-6,
74 IL-6) (Group et al., 2021a; Ulhaq and Soraya, 2020), hepatic (bilirubin) (Bangash et al., 2020) and
75 coagulatory (D-dimer, prothrombin time (PT) and activated partial thromboplastin time (APTT))
76 (Asakura and Ogawa, 2020; Iba et al., 2020; Levi et al., 2020). Details of laboratory assay methods
77 used are provided in the Supplementary section. All blood-based measurements were log-
78 transformed to transform the skewed data to approximately conform to normality. For consistency in
79 interpreting scores across blood samples, platelets values were inverted (iPlatelets) so that higher
80 scores represent lower count.

81

82 2.3. Clinical visit: cardiorespiratory assessment

83 Cardiorespiratory measurements were collected during a clinical assessment at least 12
84 weeks after discharge from initial hospitalization with COVID-19. Systolic and diastolic blood pressure
85 (BPS and BPD) were measured in lying (or seated) and standing position using automated
86 sphygmomanometry using GE Carescape V100 Dinamap Vital Signs Monitor (GE Healthcare Systems,
87 Chicago, Illinois, USA). We calculated pulse pressure (BPS-BPD) and orthostatic hypotension (e.g. BPS
88 lying – BPS standing). Lying and standing pulse pressure values were log-transformed to transform the
89 skewed data to approximately conform to normality.

90 Lung function was assessed via CareFusion Micro 1 Handheld Spirometer (Vyairre Medical
91 GmbH.; Hoechenberg, Germany) to determine peak expiratory flow (PEF), forced expiratory volume in
92 1 second (FEV1), forced vital capacity (FVC) and FEV1/FVC ratio. Measurements were repeated in
93 triplicate, with one minute rest between measurements. Each variable was log-transformed to
94 approximately conform to normality. To balance the representativeness of each data type in the
95 imputations and data-reduction stages (see Supplementary Method), spirometry measures were
96 reduced to a single variable using principal components analyses (SI Figure 2).

97 Pulse oximetry, monitored via GE Carescape V100 Dinamap Vital Signs Monitor (GE
98 Healthcare Systems, Chicago, Illinois, USA), was used to determine the heart rate and arterial oxygen
99 saturation before and following a 6-minute walk test (Bois et al., 2012; Crapo et al., 2012; PL et al.,
100 2003).

101
102

103 2.4. Research visit: neurological assessment

104 2.4.1. Image acquisition and pre-processing

105 Imaging data were acquired using a 3T Siemens Prismafit System with a 32-/20-channel head-
106 coil at the Wolfson Brain Imaging Centre (WBIC; www.wbic.cam.ac.uk) during a research visit. A 3D-
107 structural MRI was acquired on each participant using T1-weighted sequence (3D Magenitisation-
108 Prepared Rapid Gradient-Echo, 3D MPRAGE) with the following parameters: repetition time (TR) = 2
109 ms; echo time (TE) = 2.99 ms; inversion time (TI) = 880 ms; flip angle $\alpha = 9^\circ$; field of view (FOV) = 208 ×
110 256 × 256 mm³; resolution = 1 mm isotropic; accelerated factor (in-plane acceleration iPAT) = 2;
111 acquisition time, 5 min. T1 images were pre-processed using functions from SPM12 (Wellcome
112 Department of Imaging Neuroscience, London, UK) in Matlab 2020b (Mathworks,
113 <https://uk.mathworks.com/>). The T1 image was rigid-body coregistered to the MNI template, and
114 segmented to extract probabilistic maps of six tissue classes: gray matter (GM), white matter (WM),
115 CSF, bone, soft tissue, and residual noise.

116 RSFA was estimated from resting state Echo-Planar Imaging (EPI) of 477 volumes acquired
117 with 64 slices for whole brain coverage (TR = 735ms; TE = 30ms; FOV = 210mm x 210mm; resolution
118 = 2.38 x 2.38 x 2.4mm) during 5 minutes and 51 seconds. Participants were instructed to lay still, to
119 stay away and keep their eyes open, looking at a fixation cross. EPI data preprocessing included the
120 following steps: (1) temporal realignment of slices to (0,0,0) Montreal Neurological Institute (MNI) co-
121 ordinates, (2) spatial realignment to adjust for linear head motion, (3) subjected to Artifact detection
122 tools (ART)-based identification of outlier scans for scrubbing (4) coregistration to the T1 anatomical
123 image from above, (4) application of the normalization parameters from the T1 stream above to warp
124 the functional images into MNI space. We applied whole-brain independent component analysis of
125 sing-subject time series denoising to minimise motion artefacts using a priori heuristics using the ICA-
126 based Automatic Removal of Motion Artifact toolbox (AROMA; Pruim et al., 2015a, 2015b) after
127 smoothing with an 6mm FWHM Gaussian kernel.

128 The initial six volumes were discarded to allow for T1 equilibration. We quantified participant
129 motion using the root mean square volume-to-volume displacement as per Jenkinson et al (2002). A
130 general linear model (GLM) of the time-course of each voxel was used to further reduce the effects of
131 noise confounds (Geerligts et al., 2017), with linear trends and expansions of realignment parameters,
132 plus average signal in WM and CSF, CompCorr regressors, their derivative and quadratic regressors
133 (Satterthwaite et al., 2013). The WM and CSF signal was created by using the average across all voxels
134 with corresponding tissue probability larger than 0.7 in associated tissue probability maps available in
135 SPM12. A band-pass filter (0.0078-0.1 Hz) was implemented by including a discrete cosine transform
136 set in the GLM, ensuring that nuisance regression and filtering were performed simultaneously
137 (Hallquist et al., 2013; Lindquist et al., 2019). Finally, we calculated subject specific maps of RSFA
138 based on the normalized standard deviation across time for processed resting state fMRI time series
139 data (Tsvetanov et al., 2020b). RSFA maps were smoothed by a 12 mm FWHM Gaussian kernel.

140 To facilitate integrative multivariate analysis (see below), the RSFA maps were parcellated by
141 a prior cortical template into 360 bilaterally symmetric regions (Glasser et al., 2016). Regional RSFA
142 values were estimated by averaging over all voxels in each parcel.

143

144 2.4.2. Quality of life, cognition, and mental health

145 Quality of life, cognition and mental health were assessed using a set of questionnaires:
146 Generalised Anxiety Disorder-7 (GAD-7), Patient Health Questionnaire-9 (PHQ-9), Patient Health
147 Questionnaire-15 (PHQ-15), Posttraumatic Stress Disorder Checklist-5 (PCL-5) and subscores from the
148 Short Form-36 (SF-36). SF36 subscores were defined as physical functioning (SF36-PF), role limitation

149 physical (SF36-RLP), role limitation emotional (SF36-RLE), energy dimension (SF36-ED), emotional
150 wellbeing (SF36-EW), social functioning (SF36-SF), pain (SF36-P) and general health (SF36-GH).

151

152 Cognitive function and functional independence were evaluated using Montreal Cognitive
153 Assessment (MoCA, Nasreddine et al., 2005), inverted Modified Ranking Scale (mRS, Eriksson et al.,
154 2007), and Barthel Index (BI, Mahoney and Barthel, 1965). For consistency in interpreting scores
155 across questionnaires, scores for mental health questionnaires were inverted (iGAD-7, iPHQ-9, iPHQ-
156 15 and iPCL-5) so that lower values represent greater mental health problems.

157 2.5. Analytical approach

158 Statistical analysis used Matlab 2020b calling the packages as described below. We
159 performed a descriptive analysis of all the characteristics from inpatient, clinical and cognitive data
160 before integrating it with neuroimaging data as described below.

161

162 2.5.1. Group differences in cerebral microvascular health

163 We performed component-based analysis, Source-Based Cerebrovasculometry
164 (Supplementary Material) to determine spatially non-overlapping RSFA maps without using group
165 information. Subject scores for each component was predicted by group identity (Patient vs Control),
166 age, and sex in a subsequence robust multiple linear regression. The model's formula was specified by
167 Wilkinson's notation, 'rsfa ~ group*age + sex' and fitted for each component separately.

168

169 2.5.2. COVID-19 severity predicting RSFA

170 The predictive specificity of COVID-19 severity on RSFA abnormality was tested using a
171 multivariate approach. We adopted a two-level procedure (Passamonti et al., 2019a; Tsvetanov et al.,
172 2020a, 2018, 2016). In the first-level analysis, the relationships between COVID-19 Severity and RSFA
173 data were identified using partial least squares (Krishnan et al., 2011). Partial least squares described
174 the linear relationship between the two multivariate data sets, namely RSFA maps and COVID-19
175 Severity data by providing pairs of latent variables (RSFA-LV) and (COVID-19 Severity-LV) as linear
176 combinations of the original variables that were optimized to maximize their covariance. Data set 1
177 consisted of parcellated RSFA maps across all patients (45 patients x 360 nodes array, RSFA dataset).
178 Data set 2 included the COVID-19 WHO Progression scale and inpatient blood data (45 subjects x 9
179 measures array, COVID-19 Severity datasets). All variables were z-scored (mean of 0 and standard
180 deviation of 1) before entering to a permutation-based PLS analysis with 10.000 permutations to
181 determine the significance of the latent variables.

182 Next, we tested whether the identified relationship between COVID-19 Severity-LV and RSFA-
183 LV could be explained by other variables of interest and variables of no interest. To this end, we
184 performed a second-level analysis using robust multiple linear regression and commonality analysis
185 (Kraha et al., 2012; Nimon et al., 2008a). Commonality analysis partitions the variance explained by all
186 predictors in MLR into variance unique to each predictor and variance shared between each
187 combination of predictors. Therefore, unique effects indicate the (orthogonal) variance explained by
188 one predictor over and above that explained by other predictors in the model, while common effects
189 indicate the variance shared between correlated predictors. Notably, the sum of variances, also
190 known as commonality coefficients, equals the total R² for the regression model. We adapted a
191 commonality analysis algorithm (Nimon et al., 2008b) implemented in Matlab (Wu et al., 2021). This
192 model aimed to test whether the relationship between COVID-19 Severity and RSFA can be explained
193 partly or fully by systemic cardiorespiratory dysfunction or other covariates of no interest. Predictor
194 variables included subject COVID-19 Severity scores from the first level PLS and systemic
195 cardiorespiratory dysfunction (CRDPC1 and CRDPC2). The dependent variable was subjects' RSFA
196 scores from the first level PLS. Covariates of no interest included age and sex. The model can
197 therefore identify unique variance explained by each of the predictors i.e. whether COVID-19 Severity
198 LV predicts RSFA-LV over and above other predictors. Common effects of interest were the
199 cardiorespiratory-related effects, defined by the common variance between COVID-19 Severity and
200 CRDPCA1-2. Significant effects of interest were identified with nonparametric testing using 10.000
201 permutations using commonality analysis implementation in Matlab (Wu et al., 2021).

202

203 2.5.3. Exploratory analysis

204 In an exploratory analysis, the level of RSFA abnormalities was related to component
205 measures of physical, cognitive, and mental functioning (PCM) using robust regression. The PCM
206 components, defined by principal component analysis (SI Methods), we defined as dependent
207 variables in separate models. RSFA, age and sex were entered as predictors. The model's formula was
208 specified by Wilkinson's notation, 'PCM ~ RSFA + age + sex' and fitted for each PCM component
209 separately.

210 We further assessed the spatial overlap between COVID-19-related cerebrovascular burden
211 maps and a range of brain metabolic, neurotransmitter, protein expression and cell-type parameters,
212 including i) existing receptor/metabolic templates and ii) gene transcription profiling maps. Templates
213 of interest included metabolic rates of glucose, oxygen, and aerobic glycolysis (Vaishnavi et al., 2010)
214 and receptor and transmitter maps across nine different neurotransmitter systems (Hansen et al.,
215 2021b), all measured by positron emission tomography (PET). Gene expression maps (Hawrylycz et

216 al., 2012) were based on key proteins implicated in SARS-Cov-2 cellular attachment (angiotensin
217 converting enzyme-2, ACE2; neuropilin-1, NRP1; neuropilin-2, NRP2), processing (cathepsin-B, CTSB;
218 cathepsin-L, CTSL) and viral defence (interferon type 2 receptors, IFNAR2; lymphocyte antigen 6-
219 family member E, LY6E) (Iadecola et al., 2020; Yang et al., 2021). Spatial correlations were evaluated
220 using spin-based permutations preserving spatial autocorrelation (spin-permutation test) (Alexander-
221 Bloch et al., 2018; Fulcher et al., 2021).

222 Spatial covariance between the cerebrovascular burden map and gene expression across
223 9394 genes expressed in the human brain (Hawrylycz et al., 2012) was based on regularized-PLS
224 association (Blankertz et al., 2011; Ledoit and Wolf, 2004) using spin-premutation-based 10-fold
225 cross-validations (Tsvetanov et al., 2020a). The latent variable represented a spatial pattern of gene
226 expression that highly covaries with the cerebrovascular burden pattern associated with COVID-19
227 severity. Full details about the processed transcriptomic data are available elsewhere (Arnatkevičiūtė
228 et al., 2019). Genes highly expressing this pattern (i.e. high loadings) were tested against a molecular
229 atlas of human brain vasculature of 17 control and Alzheimer's disease patients (Yang et al., 2021)
230 using cell-type decomposition approach (Hansen et al., 2021a). This enabled us to test whether the
231 cerebrovascular burden-relevant genes are preferentially expressing in specific cell types i.e. testing
232 for cell-specific aggregate gene sets in eleven major canonical cortical cell classes: astrocytes (Astro);
233 brain endothelial cells (BEC); ependymal (Epend); macrophage/microglia (MacMic); meningeal
234 fibroblast (MFibro); neuron (Neuro); oligodendrocyte precursors (Opc); oligodendrocytes (Oligo);
235 pericytes (Peri); perivascular fibroblast (PFibro); smooth muscle cells (SMC). To this end, we calculated
236 the ratio of genes in each set preferentially expressed in each cell type (e.g. ratio for pericytes is
237 calculated from the number of genes preferentially expressed in pericytes divided by the total
238 number of genes). Gene sets were thresholded to include the top $n\%$ of genes with greatest loadings,
239 where n varied from 5% to no threshold. Statistical significance was determined using a null
240 distribution of ratios based on 10.000 sets of random genes (Hansen et al., 2021a).

241

242 2.6. Data availability and code

243

244 Code and composite data to reproduce manuscript figures, statistical analyses are available at
245 https://github.com/kamentsvetanov/covid19_cerebrovascularburden. Resting-state fMRI data was
246 pre-processed using SPM12 (<http://www.fil.ion.ucl.ac.uk/spm/>; Friston et al., 2007) and post-
247 processed using a GLM-like approach (Geerligts et al., 2017) available at [https://github.com/MRC-](https://github.com/MRC-CBU/riksneurotools/blob/master/GLM/)
248 [CBU/riksneurotools/blob/master/GLM/](https://github.com/MRC-CBU/riksneurotools/blob/master/GLM/). MATLAB-based commonality analysis for neuroimaging is
249 available at <https://github.com/kamentsvetanov/CommonalityAnalysis/>. Visualisation of

250 neuroimaging results was in MRICroGL (<https://github.com/rordenlab/MRICroGL>; Rorden and Brett,
251 2000) and BrainSpace (Vos de Wael et al., 2020). Neurotransmitter receptor and transporter maps
252 were available at https://github.com/netneurolab/hansen_receptors. Spin permutations (Váša et al.,
253 2018) used code available at https://github.com/frantisekvasa/rotate_parcellation. Fully-pre-
254 processed transcriptomic data was available at
255 <https://figshare.com/articles/dataset/AHBAdata/6852911> and
256 <https://github.com/BMHLab/AHBAProcessing>. The molecular atlas of the human brain vasculature
257 was available at <https://www.biorxiv.org/content/10.1101/2021.04.26.441262v1>. Cell-type
258 decomposition analysis related code was available at
259 https://github.com/netneurolab/hansen_genescognition.
260

261 3. Results

262 3.1. Participants

263 Characteristics of the 45 patients hospitalized with COVID-19 are detailed in Table 1. At
 264 hospitalisation, 30% of the patients required a mechanical ventilation (n=13) for an average of 20
 265 days; 22% of patients required vasopressors (n=10), and 9% renal replacement therapy with
 266 continuous veno-venous haemodiafiltration (n=4). The average number of days from initial symptoms
 267 to clinical and research visit was 169±35 and 180±58, respectively. Data missingness is detailed in
 268 Supplementary Results.

269

270 *Table 1. Characteristics of 45 patients hospitalised with COVID-19. n - indicates number of patients and the*
 271 *percentage of patients from the patient cohort (%), SD – standard deviation, IQR – interquartile range, kg – weight in*
 272 *kilograms, m – height in meters.*

274

275 3.2. Group differences in Cerebrovascular components

276 Using source-based cerebrovasculometry (Passamonti et al., 2019b; Tsvetanov et al., 2020b,
277 2015; Xu et al., 2009), we assessed the group differences in RSFA-based cerebrovascular components
278 between controls and patients in small set of spatially independent components ($n=8$). Each
279 participant had one value per component, *subject score*, indicating the degree to which a participant
280 expresses the spatial map of the corresponding component. One component showed significant
281 difference between the patient and control group in terms of subject scores (RSFA_{IC4}, $t = 3.12$, p
282 $= 0.003$, Figure 1), while controlling for age and sex in a robust linear regression. The spatial extent of
283 this component, RSFA_{IC4}, included voxels with high values in temporo-parietal regions, indicating that
284 individuals with higher loading values, in this case the patient group, had lower RSFA values in these
285 regions, relative to the control group (Figure 1). The other components did not differentiate patients
286 from controls (SI Analyses).

287 The spatial pattern of IC4 was consistent with the univariate approach ($r=0.46$, $p<0.001$, SI
288 Figure 5). In addition, the univariate approach revealed that the spatial pattern in RSFA associated
289 with age was highly consistent with the one reported on large-scale population-based cohorts, $r=0.42$,
290 $p<0.001$ (Tsvetanov et al., 2020b, 2015). This suggests that RSFA can detect reliably differences in
291 cerebrovascular health across various phenotypes in smaller samples. Though age is a risk factor of
292 COVID-19 severity (Verity et al., 2020) and RSFA (Tsvetanov et al., 2020c), the COVID-19 group effect
293 was not explained by individual's age, and showed only a partial overlap with the effects of age on
294 RSFA in parietal regions (SI Figure 5, Tsvetanov et al., 2020b, 2015).

302

3.3. COVID-19 Severity predicts cerebrovascular impairment

Using PLS analysis, we identified one significant pair of latent variables ($r = 0.584$, $p = 0.017$, based on a null distribution of 10,000 permutations). Variable loadings and subject scores showed a strong relationship between acute COVID-19 Severity and chronic RSFA abnormalities (Figure 2).

The RSFA latent variable (RSFA-LV) expressed negative loadings in frontal (superior frontal gyrus, middle frontal gyrus, inferior frontal gyrus and portions of the anterior cingulate) and parieto-temporal (angular gyrus, supramarginal gyrus, superior temporal gyrus, middle temporal gyrus) regions. This pattern of COVID-19 Severity-related reduction in RSFA values was mirrored in a voxel-wise analysis of RSFA maps and COVID-19 Severity component (SI Figure 5). Positive loadings in the RSFA data appeared to be in postcentral gyrus, calcarine sulcus, cuneus, and lingual gyrus. Increase in the RSFA signal in these regions may reflect increased pulsatility in neighbouring vascular and white matter territories (see SI Figure 5) as reported previously (Makedonov et al., 2016, 2013; Tsvetanov et al., 2020b, 2015). This pair of latent variables suggested that patients with higher COVID-19 Severity at acute stage have poorer cerebrovascular function in frontal and temporo-parietal regions at chronic stage. For visualisation purposes we inverted the loading values in Figure 2a so that higher values reflect poorer cerebrovascular function, i.e. higher cerebrovascular burden.

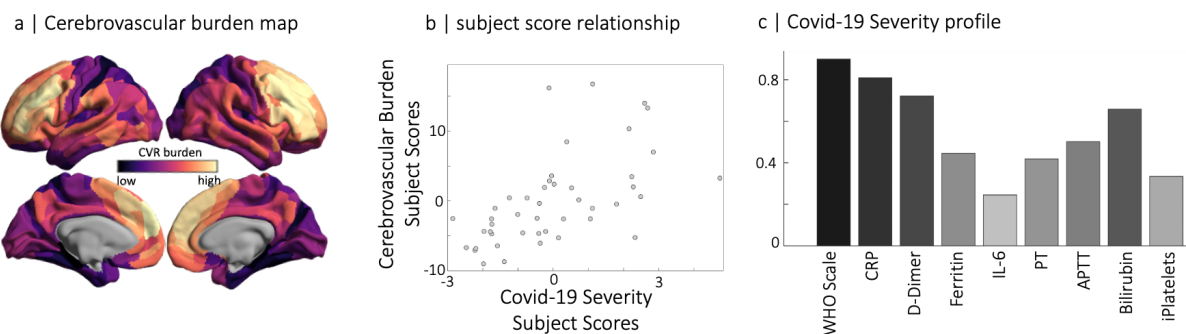

Figure 2. Partial least squares analysis of COVID-19 severity data at acute stage and RSFA-based cerebrovascular burden (CVB) at chronic stage. (panel a) Spatial distribution of parcellated RSFA values where dark to light colours are used for the strength of positive and negative correlations with the COVID-19 Severity profile (panel c). Note that regions with high cerebrovascular burden have low values in RSFA. The scatter plot in the middle panel represents the relationship between subjects scores of RSFA-latent variable and COVID-19 Severity-latent variable identified by partial least squares analysis.

To understand whether the relationship between regional RSFA impairment and COVID-19 Severity can be explained by chronic systemic cardiorespiratory dysfunction (see SI method) or covariates of no interest, we performed a second level robust regression analysis. RSFA-LV was entered as the dependent variable. COVID-19 Severity LV and the cardiorespiratory dysfunction

333 component (CRD_{PCA1} , see SI Figure 3) were entered as predictors, while age and sex were modelled as
334 covariates of no interest. All variables were normalised to have a mean of 0 and standard deviation 1.
335 Using Wilkinson notation, the regression model took the form: $RSFA-LV \sim COVID-19\ Severity-LV +$
336 $CRD_{PCA1} + CRD_{PCA2} + Age + Sex$. COVID-19 Severity was the only significant predictor of RSFA-LV in the
337 model ($r = 0.471$, $p = 0.001$ and SI Table 1), suggesting that chronic cardiorespiratory dysfunction, age
338 and sex cannot explain fully the relationship between COVID-19 Severity and RSFA abnormality.
339 Interestingly, the unique variance explained by COVID-19 Severity in the regression model was weaker
340 than the variance identified by the PLS analysis ($r = 0.584$ vs $r=0.471$ for PLS and MLR analyses)
341 suggesting that one or more of the predictors in the model explain partly some of the variance
342 between COVID-19 Severity and RSFA. Permutation-based commonality analysis with 10.000
343 permutations (SI Method) confirmed that a portion of the variance between COVID-19 Severity-LV
344 and RSFA-LV was explained by age (12% total, $p < 0.001$), cardiorespiratory dysfunction component 2
345 (CRD_{PC2} , 3% total, $p = 0.009$), and shared variance between age and cardiorespiratory dysfunction
346 component 1 (Age, CRD_{PCA1} , 20% total, $p < 0.001$), SI Table 2. COVID-19 Severity-LV remained as the
347 largest unique predictor of RSFA-LV (37% total, $p=0.006$).

348

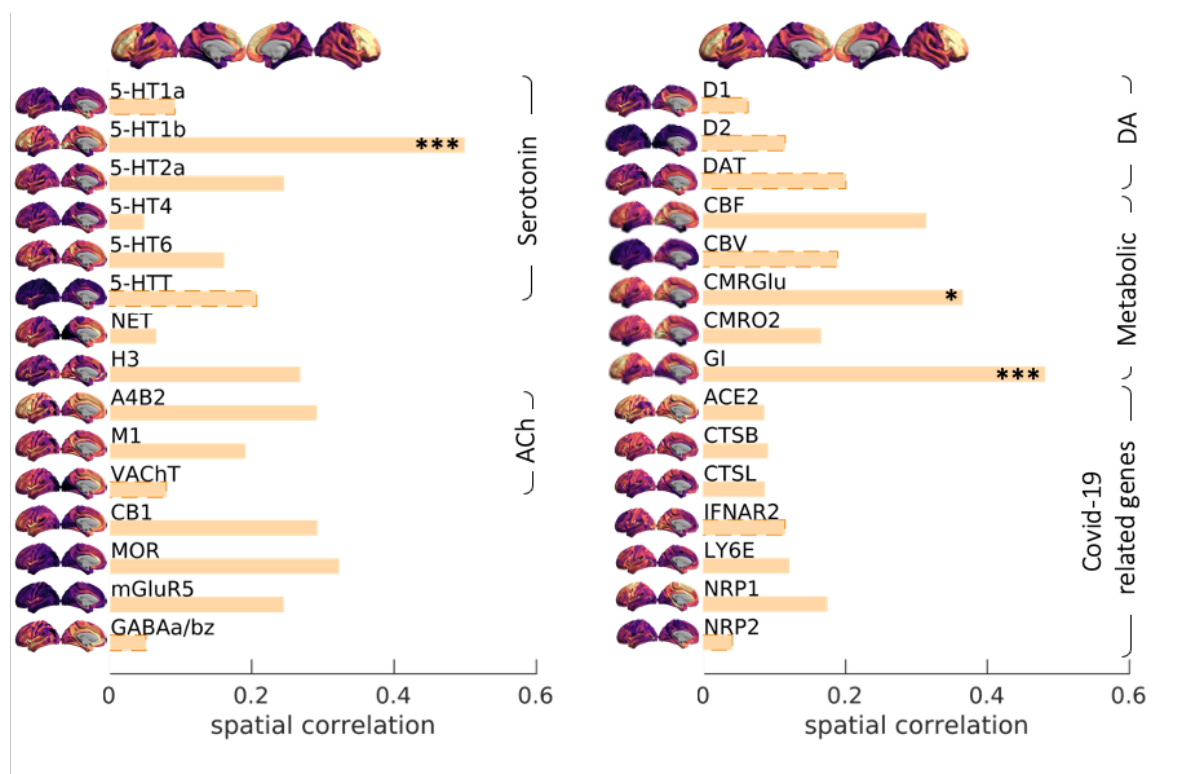

349 3.4. Exploratory analysis

350 The level of RSFA abnormalities (RSFA-LV) was related to physical, cognitive and mental
351 functioning in an exploratory analysis. RSFA-LV, age and sex were entered as predictors, while
352 cognitive and mental health components (SI Methods) were used as dependent variables in separate
353 robust regressions (Model 1: $CMH_{PCA1} \sim RSFA-LV + age + sex$; Model 2: $CMH_{PCA2} \sim RSFA-LV + age +$
354 sex). Model 1 was not significant ($p = 0.429$), while Model 2 was significant ($R^2 = 0.294$, $p = 0.002$)
355 with RSFA predicting significantly cognitive and mental health component 2 ($r = -0.352$, $p = 0.014$, SI
356 Table 3). This indicates that patients with higher RSFA abnormality have worse cognitive function, less
357 functional independence and lower quality of life (social functioning, emotional wellbeing, energy
358 dimension). The results did not change in a meaningful way by re-imputing the data ($n=5$). The
359 findings in Model 2 were confirmed using voxel-wise analysis on RSFA maps, instead of RSFA-LV (SI
360 Figure 7).

361 We next assessed the spatial overlap between COVID-19-related cerebrovascular burden maps with
362 existing neurotransmitter and metabolic maps using spatial autocorrelation-preserving permutation
363 testing (Alexander-Bloch et al., 2018). Across 21 candidate maps, we show that the cerebrovascular
364 burden map overlaps with the distribution of serotonin's vasoactive receptor 5-HT1b, aerobic
365 glycolysis and to a weaker extent cerebral metabolic rate of glucose in the brain. However, the

366 regional distribution of RSFA abnormality showed little correlation with the expression of key proteins
 367 implicated in SARS-CoV-2 cellular attachment, processing and viral defence (Figure 3). Collectively,
 368 these results demonstrate that the distribution of cerebrovascular impairment related to COVID-19
 369 severity is aligned with the spatial distribution of receptors and processes involved in the coordination
 370 of metabolic and vasoreactive responses.

371
 372

373
 374 *Figure 3. Spatial correlation between Covid19 severity-induced cerebrovascular burden map and spatial patterns*
 375 *associated with a range of neurotransmitter receptor/transporters (Hansen et al., 2021b), selective genes relevant to SARS-*
 376 *CoV-2 brain entry (Iadecola et al., 2020) and brain metabolism parameters (Vaishnavi et al., 2010). Neurotransmitter*
 377 *receptors and transporters were selective to serotonin (5-HT1a, 5-HT1b, 5-HT2a, 5-HT4, 5-HT6, 5-HTT), norepinephrine (NET),*
 378 *histamine (H3), acetylcholine (ACh, A4B2, M1, VAcHT), cannabinoid (CB1), opioid (MOR), glutamate (mGluR5), GABA*
 379 *(GABAa/bz) and dopamine (D1, D2, DAT). Metabolic maps were based on cerebral blood flow (CBF), cerebral blood volume*
 380 *(CBV), cerebral metabolic rate of glucose and oxygen (CMRglu, CMRO2) and glycemic index (GI). Selective genes relevant to*
 381 *SARS-CoV-2 brain entry included angiotensin converting enzyme-2, ACE2; neuropilin-1, NRP1; neuropilin-2, NRP2, cathepsin-*
 382 *B, CTSB; cathepsin-L, CTSL, interferon type 2 receptors, IFNAR2; lymphocyte antigen 6-family member E, LY6E. The spatial*
 383 *maps of 5-HT1b, CMRglu and Glycemic Index (GI) were significantly correlated with Covid19 severity-induced cerebrovascular*
 384 *burden map (* p-spin<0.05 (one-sided), *** p-spin<0.001). See text for more information.*

385
 386 As a final step, we used normative transcriptomics to identify genes that are normally
 387 preferentially expressed in the regions associated with COVID-19-induced cerebrovascular
 388 impairment. Regularised-PLS identified one latent component ($r=.64$, $p=0.001$, Figure 4a). Using cell-
 389 type decomposition analysis on a vascular cell-type specific gene sets, we determined the ratio of
 390 genes in each gene set preferentially expressed in one of eleven cortical cell types: astrocytes, brain

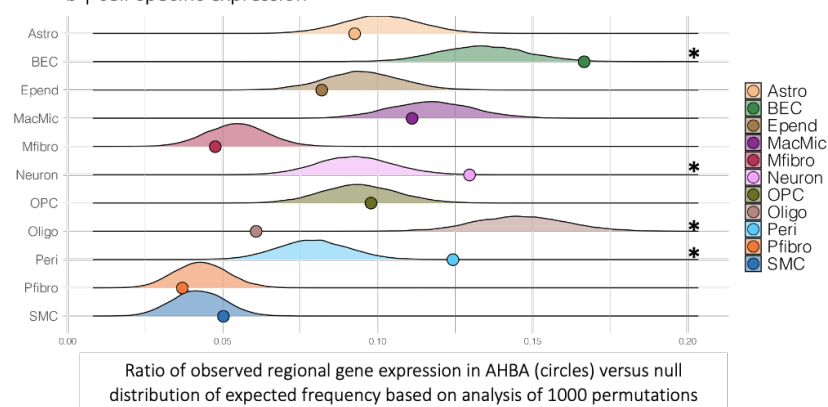

endothelial cells, ependymal, macrophage/microglia, meningeal fibroblast, neuron, oligodendrocyte precursors, oligodendrocytes, pericytes, perivascular fibroblast, smooth muscle cells. Gene-sets were thresholded to include the top 70% of genes with the highest loadings (Figure 4b), noting that results are consistent across thresholds ranging from 5 to no threshold (Supplementary Figure 8). Dominant genes were significantly more expressed in pericytes, brain endothelial cells and neurons, and significantly less expressed in oligodendrocytes. Broadly, we find evidence that areas associated with cerebrovascular impairment are enriched in for genetic signal related to neuron support (pericytes, endothelial cells and perineuronal oligodendrocytes) and neurons themselves. This dichotomy is consistent with the observations from the spatial overlap analysis.

402 *Figure 4. a, Spatial map in the transcriptome data related to the COVID-19-induced cerebrovascular burden map*
403 *(CVB). b, Cell-type decomposition was used to identify cell-type enrichment based on extent to which genes expressed the*
404 *transcriptome map in a. Gene sets for each cell-type was constructed by thresholding the top 70% of genes with greatest*
405 *loadings. Note that results were consistent across a range of thresholds, ranging from 10% to no threshold, SI Figure 8. The*
406 *ratio of genes in each gene set preferentially expressed in eleven distinct cell-types (circles) is shown against their null*
407 *distribution of a model with random selection of all genes (10,000 permutations, *p-value < 0.05). For example, pericyte's*
408 *ratio is calculated from the number of genes preferentially expressed in pericytes divided by the total number of genes. Cell*
409 *type-specificity of genes is described elsewhere (Yang et al., 2021) Astro – astrocytes, BEC – brain endothelial cells, Epend –*
410 *ependymal, MacMic – macrophage/microglia, Mfibo – meningeal fibroblast, Neuron – neuron, OPC – oligodendrocyte*
411 *precursor cells, Oligo – oligodendrocytes, Peri – pericytes, Pfibro – perivascular fibroblast, SMC – smooth muscle cells*

412

413 4. Discussion

414

415 We show that abnormalities in cerebral microvascular function, measured using resting state
416 fluctuation amplitudes (RSFA), persist many months after hospitalisation for acute COVID-19. The
417 location of these abnormalities in lateral frontal and temporoparietal regions aligns partly with
418 cerebrovascular dysfunction reported in association with ageing (Tsvetanov et al., 2020b, 2015),
419 preclinical Alzheimer's disease (Millar et al., 2020a) and systemic cardiovascular health (Tsvetanov et

420 al., 2020b). These post-COVID-19 effects were observed over and above age. They are related to
421 severity of the acute illness and the host response in the acute stage. These effects also relate to the
422 post-COVID-19 cognitive function, common indices of mental health, and quality of life at an average
423 of six months after hospitalisation.

424 In exploratory analysis, we found overlap between the regional distribution of this
425 cerebrovascular impairment and spatial distribution of the vasoreactive receptor 5-HT_{1b} and regions
426 with high metabolic demands. 5-HT_{1b} receptor is the dominant contractile 5-HT receptor in cerebral
427 arteries (Barnes et al., 2021; Nilsson et al., 1999), acting on vasoconstriction by contracting smooth
428 muscle endothelial smooth muscle directly or as moderator of other vasoconstrictors. Distinct from
429 its effects on vascular tone, the presynaptic 5-HT_{1b} receptor also has an important microvascular
430 anti-inflammatory role, both in the cerebrovascular bed and more generally. Further, its loss has
431 been implicated in progressive cognitive loss and abnormal modulation through descending
432 serotonergic outputs (Gharishvandi et al., 2020; Heijmans et al., 2021; Mitsikostas et al., 2002;
433 Sibille et al., 2007), which may be relevant for late sequelae after COVID-19.

434 The overlap of cerebrovascular impairment with the regional distribution of aerobic glycolysis
435 and glucose metabolism is spatially concordant with previous reports of hypometabolism in the
436 subacute phase of COVID-19 (Hosp et al., 2021) and neurodegeneration (Vlassenko et al., 2010). This
437 discussion provides a potential link between cerebrovascular impairment and metabolic dysfunction
438 in frontoparietal regions, which could provide important insights regarding the mechanisms of late
439 neurocognitive dysfunction following COVID-19 infection. Future work should establish whether
440 changes to the microvasculature lead to hypometabolism (Shi et al., 2016) or the vulnerability of brain
441 physiology in chronic phase is due to hypoxic and hypometabolic exposure in the subacute phase
442 (Vestergaard et al., 2020). Collectively, these results demonstrate that the distribution of chronic
443 cerebrovascular impairment related to COVID-19 severity maps to the spatial distribution of
444 processes involved in coordinating metabolic and vasoregulatory responses associated with changes
445 in brain function and cognition.

446 We also tested whether genes highly expressed in regions with COVID-19-induced cerebrovascular
447 change are preferentially expressed in specific cell types using a molecular atlas of human brain
448 vasculature (Yang et al., 2021). Dominant genes were overexpressed in pericytes, brain endothelial
449 cells and neurons, but underexpressed in oligodendrocytes. The evidence that genes implicated are
450 enriched in pericytes and endothelial cells is particularly interesting. Brain endothelial cells are
451 susceptible to direct SARS-CoV-2 infection through flow-dependent expression of ACE2. The SARS-

452 CoV-2 S protein binding triggers a gene expression profile that may compromise the neurovascular
453 interface (Kaneko et al., 2021). On the abluminal aspect of the neurovascular interface, pericytes
454 express abundantly the angiotensin-converting enzyme-2 (ACE2) receptor (He et al., 2020). The
455 expression can be increased with by exposure to the viral S protein, and importantly, potentiated in
456 combination with hypoxia (Khaddaj-Mallat et al., 2021), a mechanism which could account for the
457 modulation of RSFA abnormality by disease severity in our cohort.

458 Given this biological context the correlation of RSFA abnormalities with disease severity is
459 open to two potential interpretations. One possibility is that these changes in cerebrovascular
460 regulatory integrity are the consequence of direct viral invasion; while the other is that these
461 abnormalities are a consequence of the inflammatory host response, which is a consequence of, but
462 may not scale precisely with, viral infection. Spatial correlation of RSFA abnormality with the
463 expression of ACE2 and Neuropilin-1, or of genes involved in cellular responses to viral invasion would
464 have provided supportive evidence of a role for direct viral infection as a mechanism, but we were
465 unable to demonstrate such a correlation. This negative finding favours the explanation that host
466 inflammatory responses may be drivers in this context, and merit further investigation as mechanisms
467 of late cerebrovascular regulatory dysfunction. It is important to acknowledge that our correlations
468 with regional gene expression are based on expression patterns in normal brain, and that these
469 expression patterns may be substantially altered by the inflammatory milieu that prevails in the
470 context of COVID-19. Consequently, direct examination gene expression patterns in late COVID-19
471 survivors would provide additional insights.

472
473 Our study has several limitations. We are limited by the relatively small sample size, and by
474 the absence of longitudinal imaging data. We also do not draw any causal inferences from the
475 associations we observe. However, the demonstration of functional microvascular abnormalities
476 following COVID-19 is important to understand the potential mechanisms of persistent cognitive and
477 mental health problems. The association of microvascular abnormalities with late outcomes of
478 relevance to patients, and the fact that they represent an easily accessible biomarker, suggest both a
479 potential therapeutic target and/or a biomarker of treatment effect in interventional studies. It
480 remains to be shown whether the localisation of RSFA abnormalities to regions rich in 5HT-1b
481 receptors is a consequence of overactivity of these receptors (resulting in low cerebral blood flow),
482 underactivity or loss of these receptors (resulting in vasoparalysis and/or inflammation), or a
483 manifestation of flow-metabolism mismatching with inadequate substrate and oxygen delivery. This is
484 relevant as potential therapeutic agents that are available to modulate both 5HT-1b function (Barnes
485 et al 2021) and inflammatory response (Zhang et al., 2020) (Group et al., 2021b; Zhang et al., 2020).

486

487 In summary, we demonstrate that the severity of acute COVID-19 predicts cerebrovascular
488 impairment six months later. The cerebrovascular abnormality was associated with worse cognitive
489 function, mental health, functional recovery, and quality of life months after hospitalisation. Localised
490 across lateral frontotemporoparietal regions, we show that its genetic signature shapes the
491 composition of cell-types and metabolism. Collectively, these results implicate the COVID-19-related
492 vulnerability of brain systems differentially relying on diverse physiology and cell biology in support of
493 their functional specialisation.
