12

13 **Abstract**

14 **Background** To systematically identify cell types in human ligament, investigate how
15 ligamental cell identities, functions, and interactions participated the process of
16 ligamental degeneration and explore the changes of ligamental microenvironment
17 homeostasis in the disease progression.

18 **Methods** Using single-cell RNA sequencing and spatial RNA sequencing of
19 approximately 49356 cells, we created a comprehensive cell atlas of healthy and
20 degenerated human anterior cruciate ligaments. We explored the variations of the cell
21 subtypes' spatial distributions and the different processes involved in the disease

22 progression, linked them with ligamental degeneration process using computational
23 analysis.

24 **Results** We identified new fibroblast subgroups contributed to the disease and
25 mapped out their spatial distribution in the tissue and revealed two stages of the
26 degenerative process. We compared the cellular interactions between different tissue
27 states and identified important signaling pathways may contribute to the disease.

28 **Conclusion** This cell atlas provides the molecular foundation for investigating how
29 ligamental cell identities, biochemical functions, and interactions contributed to the
30 ligamental degeneration process. The discoveries revealed the pathogenesis of
31 ligamental degeneration at single-cell and spatial level which is characterized by
32 extracellular matrix remodeling. Our results provide new insights into the control of
33 ligamental degeneration and potential clues to developing novel diagnostic and
34 therapeutic strategies.

45 **Introduction**

46 With the increasing aging of the world's population, most of us crave a healthy
47 and long life(Beard & Bloom, 2015). Good musculoskeletal healthy is essential to
48 people to live independently in the society throughout their life course(Briggs et al.,
49 2016). Skeletal ligaments, an important part of the musculoskeletal, are defined as
50 dense connective tissue that span the joint and then fixed at both ends of the bone.
51 One of the main functions of ligaments is mechanical as they passively maintain joint
52 stability and assist in guiding of those joints through their normal range of motion
53 when a tensile loading is applied(Frank, 2004). The knee is the largest and most
54 complicated hinge joint associated with weight bearing in the human body. The
55 anterior cruciate ligament (ACL) is crucial for knee kinematics, especially in rotation,
56 and functions as an anterior/posterior stabilizer(Fleming, 2003). ACL degeneration
57 can gradually result in chronic knee pain, instability and even poor life
58 quality(Thompson et al., 2015). ACL rupture is a risk factor for cartilage degeneration
59 and the development of osteoarthritis (OA)(Roos, Adalberth, Dahlberg, & Lohmander,
60 1995). It has been reported that aging-related degenerative changes in the ACL might
61 also contribute to OA occurrence and progression(Loeser, 2010), but mechanisms of
62 ACL aging and degradation are remain unclear.

63 The extracellular matrix (ECM) is the physical basis for the biological functions
64 of ligaments, and ACL degeneration is accompanied by alterations in the ECM. The
65 ECM of ACL consist of collagen types I, II, III, and V, elastin, and

66 proteoglycans(Laurencin & Freeman, 2005), and collagen type I is a major
67 determinant of tensile strength(Corps et al., 2006). ACL degeneration is characterized
68 by disorganization of collagen fibers, cystic changes, mucoid degeneration and
69 chondroid metaplasia(Hasegawa et al., 2012). Different types of pathological changes
70 correspond to different ECM alterations. For example, mucoid degeneration reflects
71 degradation of collagen and deposition of new glycosaminoglycans and cystic
72 changes represent devoid of ECM in the diseased area(Hasegawa et al., 2012). It has
73 been reported that some regions in the degenerated ACL have decreased type I
74 collagen, whereas type II, III, and X collagen and aggrecan are significantly increased,
75 and this abnormal ECM production can lead to biomechanical fault(Hasegawa et al.,
76 2013; Hayashi et al., 2003). In recent years, many scholars have paid attention to the
77 degeneration mechanism of ligaments. TGF β 1, a member of the TGF superfamily, can
78 be used to induce chondrogenic differentiation of ligament-derived stem cells in
79 vitro(Schwarz et al., 2019) and is considered to be an essential molecule contributing
80 to chondroid metaplasia. Some reports suggested that complement cascade could lead
81 to ECM catabolism and contribute to ligament degeneration(Busch et al., 2013;
82 Schulze-Tanzil, 2019).

83 There are various types of cells in the ligament(Kharaz, Canty-Laird, Tew, &
84 Comerford, 2018) and building a detailed ligamental cell landscape is essential to
85 understand ligamental characteristics and underlying pathogenesis of ACL
86 degeneration and OA. As a result of the continuous technological innovation,
87 single-cell RNA sequencing (scRNA-seq) is recognized as a significant tool for

88 depicting cellular heterogeneity(Wen & Tang, 2018; Zeng et al., 2019). Spatial RNA
89 sequencing (spRNA-seq) is a recently developed revolutionary technology. It
90 combined the advantages of the comprehensive analysis of bulk RNA sequencing and
91 in situ hybridization to provide complete transcriptome data with spatial
92 information(Li & Wang, 2021). Here, we performed scRNA-seq and spRNA-seq to
93 obtain an unbiased atlas of ACL cell clusters. Our findings provide a better
94 understanding of the inherent heterogeneity, construct the classifications of fibroblasts
95 and profile the spatial information of identified cell clusters in the ACL. Notably, we
96 also identified the cell interactions during the disease process and demonstrate the role
97 of FGF and TGF- β signaling pathways in ligament degeneration. Thus, our study
98 reveals the cellular landscape of the human ACL and provides insight that could help
99 to identify therapeutic targets for human ligament degeneration.

100

101 **Methods**

102 Human ligament cell sample preparation

103 The ligament specimens were collected from four joint replacement patients with
104 osteoarthritis (degenerated ACLs) and four amputation patients with osteosarcoma
105 (healthy ACLs).

106 All specimens removed were placed immediately in Dulbecco modified Eagle
107 medium (DMEM) free of antibiotics and FBS under 4°C. Ligament samples were
108 rinsed in precooled PBS and then were cut into 1 mm³ pieces. Containing Collagenase
109 type I (2 mg/ml) and 0.25% (w/v) trypsin DMEM was used to digest the specimens

110 for 1 h at 37°C using a Thermomixer at 1200 rpm (Eppendorf, Hamburg, Germany).
111 After that, Ham's F-12 media containing 10% FBS was added to stop the process of
112 digestion and then the digested tissue passed through a 100 µm cell strainer. Finally,
113 after centrifugation, cells were collected for subsequent batch analysis.

114

115 Single-cell RNA-seq analysis

116 The raw single cell sequencing data was mapped and quantified with the 10 ×
117 Genomics Inc. software package Cell Ranger (v5.0.1) and the GRCh38 reference
118 genome. Using the table of unique molecular identifiers produced by Cell Ranger, we
119 identified droplets that contained cells using the call of functional droplets generated
120 by cell ranger. After cell containing droplets were identified, gene expression matrices
121 were first filtered to remove cells with > 5% mitochondrial genes, < 250 or > 8000
122 genes, and < 500 UMI. Downstream analysis of Cellranger matrices was carried out
123 using R (4.1.3) and the Seurat package (v 4.1.0, satijalab.org/seurat). In total, 49356
124 cells with an average of 2435 genes per cell were selected for ongoing analysis. Of
125 these single cells, 24721 were obtained from lesions ligament, included L2, L5, L6 and
126 L8. The remainder were cells from healthy and included L1, L3, L4 and L10.

127

128 Single-cell trajectory analysis

129 We used the Monocle3 v. 2.8.0 R package to infer a hierarchical organization part of
130 fibroblasts, to organize these cells in pseudotime. We took these subpopulations from
131 the Seurat data set from which we reperformed shared nearest neighbor clustering and

132 differential expression analysis as described previously. We then selected the
133 differentially expressed genes based on fold-change expression for Monocle to order
134 the cells using the DDRTree method and reverse graph embedding. We find gene
135 co-expression modules according to the trend of gene expression, and show the
136 relationship between cells and modules in the form of heat maps.

137

138 Ligand-receptor interaction model.

139 We used the ligand-receptor interaction database from cellchat database to determine
140 potential ligand-receptor interactions between fibroblast subpopulations and other cell
141 types. The expression data were preprocessed for subsequent cell-cell communication
142 analysis. The ligand or receptor that is overexpressed in a class of cells is first
143 identified, and the gene expression data is then projected into a protein-protein
144 interaction network. Whenever a ligand or receptor is overexpressed, the
145 ligand-receptor interaction is recognized. CellphoneDB is based on the expression of
146 a receptor in one cell type with a ligand in another cell type, resulting in rich
147 receptor-ligand interactions between two cell populations. For the gene expressed by
148 the cell population, the percentage of cells expressing the gene and the average gene
149 expression were calculated. The gene was removed if it was expressed only in 10% or
150 less of the cells in the population (the default value is 0.1).

151

152 Spatial-transcriptome analysis

153 We used L1, L8 samples for spatial transcriptome analysis. We performed the Seurat

154 standard analysis. Machine prediction and marker gene methods were used to
155 determine the cell type and used SCTransform for standard analysis of the data. First,
156 we determine it is specific enough to finding a topic profile (similar to a feature vector)
157 for each cell type, and then deconvolved the information by cell type and
158 superimposed it onto the slice in pie chart form.

159

160 Deconvolution analysis

161 SCDC (v 0.0.0.9000) tool combined with single cell data was used to deconvolve bulk
162 RNAseq data for cell type and content proportion analysis bulk RNAseq data. The
163 bulk RNAseq data is also our own data. Histogram and heat map can be drawn for the
164 predicted data, and the proportion of cell type content can be compared between
165 groups. Then we used GSVA (v 1.42.0) to calculate the same data and draw heat maps
166 to aid the analysis.

167

168 Statistical analysis

169 Nonparametric Wilcoxon rank sum test was used to analyze the differences between
170 two groups. All statistical analyses were performed in R or GraphPad Prism (version
171 5.0). Statistical significance was defined as * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

172

173 **Results**

174 1. Comprehensive scRNA-seq analyses resolve the major cell types in the human
175 normal and degenerated ligament

176 To decipher cellular heterogeneity and construct the cell landscape for ligament
177 degeneration, we performed single-cell transcriptomic profiling of cells from four
178 healthy and four degenerated ACL. The characteristic pathological findings in the
179 ACL of OA were identified by arthroscopy (figure1 A and B). In the normal group,
180 the ligaments are white stripes with clear structure, and blood vessels can be seen on
181 their surfaces. In the degenerated group, the ligaments were swollen, the structure was
182 disorganized, and the color of the tissue was dark. From the images of knee MRI, we
183 can also find that the signal of normal ACL on T2 phase is uniform and the structure
184 is clear, while the signal of the ACL in the degenerated group is mixed, and the clear
185 structure cannot be distinguished (supplementary figure 1 A and B). After rigorous
186 quality control, we obtained the transcriptomes of 49356 cells (normal: 24635
187 degenerated: 24721) and then employed differential gene expression analysis to
188 discern cluster-specific markers. We firstly used principal component analysis (PCA)
189 to reduce the dimension, and then we adopted uniform manifold approximation and
190 projection (UMAP) method to conduct next analysis. Unbiased clustering based on
191 UMAP identified four cell classes and histronic lineage-defining genes were detected,
192 including endothelial cells: PECAM1, VWF, and PLVAP (3862, 7.83%), fibroblasts:
193 DCN, LUM, and COL1A2 (32644, 66.14%), immune cells: PTPRC, SRGN, and
194 CD163 (8021, 16.25%), and pericytes: ACTA2, MCAM, and RGS5 (4829, 9.78%)
195 (figure 1 C-F and supplementary figure1 C). According to figure1 I, we were able to
196 further confirm that the selected cell markers could well identify various cell types.
197 UMAP plots and stacked bar plots in figure 1G described the distributions of cells in

198 the healthy and degenerated samples. We can conclude that, in general, fibroblasts are
199 the main cell type in both normal and degenerated ligaments and the degenerated
200 group had higher immune cells ratio and lower pericytes ratio compare with the
201 normal group. We next analyzed the number of differentially expressed genes (Degs)
202 between healthy and degenerated ligament clusters. The results demonstrated that the
203 fibroblast had the largest difference, implying that fibroblasts undergo significant
204 changes during the degenerative progress (figure 1 H). We also collected normal as
205 well as degenerated ligament specimens for bulk sequencing and performed
206 deconvolution analysis between bulk sequencing results and scRNA-seq results. The
207 results illustrated that scRNA-seq samples were in good agreement with bulk
208 sequencing samples (figure 1 J and K). After that, we verified the top 5 genes that
209 were highly expressed in the degenerative state of the 4 cell subsets in the bulk
210 sequencing results and these results also have a high consistency (supplementary 1
211 D-G).

212

213 2. Characterizations of subpopulations of ligament fibroblasts between different 214 kinds of tissue states

215 Because fibroblasts are known to play a vital role in ECM homeostasis and the
216 degeneration of the ligament and undergo remarkable changes during the process of
217 ligament degeneration, we next conducted further analysis of fibroblasts in normal
218 and degenerated ligaments. We subclustered fibroblasts and identified 10 subsets
219 (Fib.1-Fib.10) (figure 2A). The distribution shown in figure 2B indicated that the

220 batch effects are resolved well. As illustrated in figure 2C, we obtained the cell
221 proportions of the fibroblast subpopulations between normal and diseased groups. We
222 can conclude that the ratio of fibroblast subclusters varied greatly between these two
223 groups. The ratio of Fib.1, Fib.2, Fib.8, and Fib.9 in the diseased group was obviously
224 higher than that in the healthy group, and the ratio of Fib.3, Fib.4, and Fib.7 in the
225 healthy group was obviously higher compare to the diseased group. The proportion of
226 remaining fibroblast subclusters did not differ significantly between the two groups.

227 According to the analysis of Degs among these fibroblast subgroups, we tried to
228 reveal the identity of each subpopulation (figure 2D). Combined with the analysis of
229 the proportion of cell subclusters, we inferred that Fib.1 and Fib.2 are ECM
230 remodeling associated fibroblasts as they highly expressed the genes related to ECM
231 components and ECM decomposition such as COL1A1, CTHRC1, COL3A1, FBLN1,
232 MMP2, MMP14 and TPPP3. From the perspective of ECM synthesis, Fib.1 and Fib.2
233 are slightly different. Fib.1 highly expressed the collagen related genes, but Fib.2
234 highly expressed the genes related to synthesis of connexins. Fib.3 expressing
235 metallothionein family genes such as MT1X, MT1E, and MT1M is a population of
236 homeostasis-associated fibroblasts with defensive functions. Fib.4 expressing genes
237 associated with formation and organization of the ligamental ECM such as ANGPTL7,
238 MYOC, CILP2 and THBS1 is a group of resident fibroblasts that function normally.

239 Fib.5 is a cluster of structural fibroblasts within the ligament as they highly expressed
240 multiple collagen-related genes such as COL3A1, COL6A1, COL5A1, COL1A1, and
241 TGFVBI. Fib.6 is a cluster of chondrocytes as they highly expressed cartilage related

242 genes such as COL2A1, FMOD, CHAD, ACAN, and CILP2. We cannot define Fib.7
243 well, because they expressed Degr without specific tags. Fib.8 is a group of cycling
244 cells as they highly expressed cell cycle related genes such as CENPF, TOP2A, and
245 MLI67. Fib.9 is a group of inflammation related fibroblasts as they highly expressed
246 CXCL14, CXCL12, C3, and C7. Fib.10 may have the function of damage repair as
247 they highly expressed anti-inflammation and anti-ECM decomposing associated genes
248 such as PRG4, DEFB1, TIMP3, and HBEGF.

249 For further in-depth investigation of changes in ligamental fibroblasts during the
250 degeneration process, we performed the Degr analysis in the whole fibroblast
251 population between the normal and degenerated ligaments. We observed genes
252 upregulated in the degenerated group such as CFD, SPP1, COL1A2 and COL3A1,
253 which were related to scar healing and ECM remodeling (figure 2E). Gene Ontology
254 (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analysis were
255 conducted for further functional interpretation of these Degr. The results illustrated
256 that the upregulated genes in diseased group were enriched for the terms
257 “extracellular region”, “TGF-beta signaling pathway” and “Complement and
258 coagulation cascades” (figure 2F). Gene Set Enrichment Analysis (GSEA) also
259 demonstrated that ECM associated signaling, ECM binding and ECM structural
260 constituent, were activated in the degenerated group, which implied that the changes
261 of ECM play an important role in the ligament degeneration (figure 2G). And then by
262 building gene interaction networks, we identified that genes upregulated in
263 degenerated groups were concentrated in two parts, ECM-receptor interaction and

264 leukocyte trans-endothelial migration, which once again proved the significant
265 function of ECM remodeling and immune inflammation in the disease process (figure
266 2H).

267

268 3. Dynamic transcriptional changes in ligamental degeneration

269 To gain insight into the cellular progression of fibroblast subclusters during the
270 disease process, we performed cell trajectory analysis, revealing that two significant
271 routes in the process of degeneration. Five fibroblast subclusters, including Fib.2,
272 Fib.4, Fib.5, Fib.9, and Fib.10, were involved in reconstruction the disease trajectories
273 using Monocle 3, an algorithm for the reconstruction of lineage programs based on
274 similarity at the transcriptional level(Cao et al., 2019). We set Fib.4 and Fib.5 as the
275 starting point of the trajectories due to they are structural fibroblasts with high
276 expression of ECM component genes and represent normal ligamental functions well,
277 and then computed pseudotime for cells along the inferred developmental axis (figure
278 3A and B). More specifically, Fib.4 and Fib.5 were predicted to transformed into two
279 distinct cell fate, including the cell fate1, which includes Fib.2 and Fib.9, and the cell
280 fate2, which includes Fib.10. With this in mind, we tried to explore the genic
281 dynamics that distinguished these two cell fates. The expression profile of cell fate1
282 showed increasingly high expression of genes (CXCL12, MMP2, MMP14, C7)
283 related to “leukocyte trans-endothelial migration”, “cellular response to chemokine”,
284 and “inflammatory response pathway”. Along with the cell fate2, we observed
285 gradually high expression of ECM organization and skeletal muscle tissue

286 development related genes (FOS, EGR1, FGF10, FN1) (figure 3C-H).
287 To investigate gene expression dynamics along the trajectories, we group genes that
288 varied between cell clusters into Module 10 using Louvain community analysis. We
289 can observe the aggregated expression of each module in the figure 3I. We identified
290 that the expression of genes in module 3 was gradually elevated along the cell fate1
291 and gradually declined along the cell fate2, which were enriched for genes related to
292 rheumatoid arthritis, antigen processing and presentation and complement activation.
293 In contrast, the expression of wound repair and ECM assembly related genes were
294 gradually elevated along the cell fate2 but declined along the cell fate1, such as
295 ADAM12, HS3ST3A1, FN1, and SERPINE2 in module 5 (figure 3I-K). According to
296 these pseudotime analysis results, we inferred that there are two opposite dynamic
297 trajectories in the process of ligament degeneration, one is the progressive damage
298 process of complement inflammation leading to the continuous progression of the
299 disease, and the other is the process of repairing the damage to delay or even reverse
300 the disease process.

301

302 4. Characterization of stromal cells in coordinating ligament microenvironment
303 during degeneration progression.

304

305 Besides fibroblasts, various endothelial cells (ECs) and immune cells also play
306 significant roles in the occurrence and development of ligament degeneration.

307 In our ligament samples, we identified seven clusters of blood-vessel derived cells

308 including five clusters of ECs (EC1-5) and two clusters of pericytes (pericyte1 and
309 pericyte2). Fig 4A shown the distribution of EC1 expressing high level of ACKR1 is a
310 population of venous ECs; EC2 highly expressed COL4A1, COL4A2, H19 was
311 related to anti-angiogenesis; EC3 highly expressed genes associated with ECM
312 organization and we inferred this cluster related to damage repair. EC4 expressing
313 high level of CCL2, CCL8, STEAP4 and SYNPO2 is a cluster of ECs related to
314 inflammatory chemotaxis. EC5 is a cluster of lymphatic ECs. As for pericytes, we
315 identified two populations expressed pericyte markers ACTA2, MCAM. Pericyte1
316 highly expressed myocyte related genes such as MYH11, MUSTN1 and LBH, which
317 implied that this cluster may have myocyte-like properties. Pericyte2 highly expressed
318 fibroblast markers such as COL1A1 and COL3A1, which implied that this cluster
319 may have fibroblast-like properties (figure 4G). We next compared the proportions of
320 these 7 clusters between normal and diseased ligament (figure 4C and D). The results
321 illustrated that most ECs subsets were elevated in the diseased group, implying
322 increased angiogenesis during ligamental degeneration. The ratio of pericyte1 in the
323 diseased group was higher than that in the healthy group, but the ratio of pericyte2
324 was lower. Increased ratio of pericyte1 may change the tissue biological properties, as
325 ligament was dominant by fibroblast. To gain more biological insights underlying ECs,
326 we performed Degs analysis between normal and degenerated groups (figure 4E).
327 Combined with the result of enrichment analysis and GSEA analysis, we identified
328 that ligamental ECs upregulated inflammation and complement related genes, such as
329 C1QA, PLA2G2A, and ECM related genes such as PRG4, VIM, and POSTN during

330 degeneration procession (figure 4H). The term “inflammation mediated by chemokine
331 and cytokine signaling pathway” and “TGF-beta signaling pathway” activated in
332 diseased group also implied that the inflammation and ECM remodeling have
333 significant roles in the disease process (figure 4F).

334 As an indispensable cellular component in the ligament, we identified six
335 subpopulations of immune cells, including basophils, CD8⁺ NKT-like cells,
336 macrophages, memory CD4⁺ T cells, memory CD8⁺ T cells, and myeloid dendritic
337 cells (figure 4I and J). From figure 4K and L, we can conclude that macrophages are
338 the most abundant immune cells in both normal and diseased groups and compared
339 with the normal group, only the proportion of macrophages was increased in the
340 degenerated group. We explored the gene profiling change of macrophages in the
341 process of degeneration. As is shown in the violin plot figure 4M, we suggested that
342 ECM remodeling related genes have higher expression level in the diseased group,
343 such as PRG4, FN1 and HTRA1. The enrichment analysis also implied that ECM
344 organization and complement and coagulation cascades were activated in the
345 degenerated ligament, which was basically consistent with the results of ECs analysis
346 (figure 4N).

347

348 5. Putative signaling network for the intercellular crosstalk regulating the
349 microenvironment homeostasis during ligamental degeneration

350 Elucidating the explicit interaction among fibroblasts, ECs and immune cells in the
351 ligamental microenvironment will shed light on the mechanisms of the pathogenesis

352 of ligamental degeneration. CellphoneDB and CellChat analysis were used to
353 investigate the signaling network among the main cell clusters in the ligament. The
354 heatmap illustrated the intensity of interactions among different cell clusters. From the
355 results, we can find that in addition to interactions within fibroblast subclusters,
356 cell-cell cross-talks were mainly between fibroblast subpopulations and ECs and
357 between fibroblast subpopulations and macrophages. At the same time, we can find
358 that fibroblast subsets dominated by the diseased group had stronger interaction
359 associations with other cells, which implied that there are stronger and more complex
360 interactions in degenerated ligaments (figure 5A).

361 To determine the important factors, we further analyzed the intercellular signaling
362 networks of FGF and TGFB. Interestingly, Fib.9 was obviously involved in FGF
363 signaling, both autocrine and paracrine (figure 5B). Fibroblasts were the leading
364 receiver of FGF signals, as expected. Through the violin plot, we identified that Fib.9
365 acts on FGFR1 located on each fibroblast subpopulation by expressing FGF7 and
366 FGF signaling pathway can promote pathological proliferation of cells and participate
367 in scar repair (figure 5D). We inferred that the FGF signaling network may disrupt the
368 homeostasis of fibroblasts in the ligaments and promote the progression of ligamental
369 degeneration. Moreover, the TGF- β pathway was involved in many cell-cell
370 interactions among fibroblasts subpopulations and macrophages via TGFB1-TGFBR1
371 or TGFB1-TGFBR2 (figure 5C and E). As shown above, fibroblasts of the
372 degenerated group highly expressed PRG4, COL3A1, and SSP1 and these genes all
373 important downstream target of TGF- β , which participate in the process of ECM

374 remodeling. Hence, we suggested that TGFBI is a key gene and macrophages promote
375 the development of the disease may through this molecule.

376

377 6. SpRNA-seq of ligament deciphering the spatial interactions of cell subclusters

378 For further insight, multi-angle interpretation of the cell composition changes that

379 occurred in ligament degeneration, we performed spRNA-seq on normal and

380 lesioned ligaments. Firstly, by using feature marker transfer method, we mapped the

381 individual subsets identified by single-cell sequencing into spatial transcriptome data.

382 The heatmap illustrated that Fib.6, as a representative of fibroblasts in normal

383 ligament tissue, was widely distributed in L1 and the amount was significantly higher

384 than that in L8. The number of Fib.13, as a representative of fibroblasts in

385 degenerated ligament, in L8 was obviously higher than that in L1 (figure 6A-D). We

386 also examined the immune cells and ECs. As expected, there were more immune cells

387 and ECs in L8 than in L1, implying immune infiltration and vascular hyperplasia were

388 presented in the degenerative specimens (figure 6E-J). These results are consistent

389 with those obtained by single cell sequencing. After that, we performed spotlight

390 analysis in these two groups. All cell subsets are rendered in four colors, with red

391 being the fibroblast subsets specific to the disease group. Finally, we hide the areas

392 that are not red in both samples. We can find that the red region in L8 was widely

393 distributed and the area was significantly higher than that in L1 group. And after

394 careful observation, we found that almost all the red dots had yellow and black areas

395 (figure 6K and L). This indicates that some fibroblast subpopulation specific to the

396 diseased group are adjacent to endothelial and immune cells in the degenerative state.
397 The proximity of different cells in space makes it possible for them to interact with
398 each other. Therefore, this further provided strong evidence for the results of our
399 single-cell interaction analysis

400

401 **Discussion**

402 ACL degeneration can contribute to cartilage injury and even OA onset and
403 progression and may put a great burden on the normal life of many
404 patients(Georgoulis et al., 2010; Hasegawa et al., 2012). But the mechanisms of this
405 disease are not well characterized and treatments to prevent or treat ACL degeneration
406 are scarce and not effective(Shane Anderson & Loeser, 2010; Tozer & Duprez, 2005).
407 Healthy and degenerated ACL tissues include multiple cell subpopulations with
408 diverse genetic and phenotypic characteristics. How this heterogeneity emerges in
409 development degeneration remains unclear. Herein, we built a single-cell atlas of
410 normal and degenerated human ACL and explored the characteristics and key
411 regulatory pathways of distinct fibroblast subtypes. These findings will help us
412 understand the pathogenesis of ACL degeneration in depth, and provide potential
413 targets for clinical therapies of this disease.

414 Fibroblasts are increasingly considered as dominating cell types in ligaments and
415 central mediators of ligamental degeneration, and here we identified 10 fibroblast
416 subpopulations in human normal and degenerated ACL samples by using scRNA-seq.
417 Further cluster analysis profiled characteristics of each subclusters and combined with

418 the cell proportion analysis we found that pro-inflammation and ECM remodeling
419 related fibroblast subgroups were significantly increased in the degenerative
420 ligamental tissues, which implied that inflammation and ECM remodeling are key
421 events in the disease process. Through comparing the Degs of fibroblasts between
422 degenerative and healthy conditions, we found that ECM related genes were
423 upregulated in the diseased group such as FN1, COL3A1, PRG4 and SPP1. The
424 results of enrichment analysis and GSEA also illustrated that ECM related pathways
425 were activated in the degenerated group, which suggested that the modules of ECM
426 play an important role in the process of ligamental degeneration. According to the
427 gene interaction analysis, two gene modules were activated in the diseased group,
428 leukocyte trans-endothelial migration and ECM-receptor interaction. These findings
429 were consistent with previous studies which suggested that ligament inflammation
430 and ECM changes contribute to ACL degeneration(Busch et al., 2013; Hasegawa et al.,
431 2012). It is due to the changes and remodeling of the ECM in the degenerative
432 ligament tissue that the biomechanical changes of the ligament are caused and
433 eventually may result in the rupture of the ligament. From the pseudotime analysis,
434 we identified two cell fates in the ligamental degeneration. Cell fate 1 represents a
435 progressive process of disease characterized by inflammatory damage and
436 extracellular matrix degradation. Cell fate 2 implies a chronic repair process for the
437 disease characterized by ECM remodeling, ligament development, and damage repair.

438 Immune cells are closely related to ligamental degeneration(Kim-Wang et al.,
439 2021). We analyzed the heterogeneity of immune cells in ACL using single-cell RNA

440 sequencing. The results illustrated that macrophages are dominating immune cells in
441 ACL and inflammation related genes PLA2G2A and ECM related genes PRG4, FN1,
442 and HTRA1 were upregulated in the macrophages of the diseased group. Enrichment
443 analysis also revealed that complement and ECM related pathways were activated in
444 the degenerated group. This implied that macrophages highly expressed ECM and
445 inflammation associated genes in the ligamental degeneration progression. So, we
446 suggested that macrophages may contribute to the ligamental degeneration. We also
447 identified two types of pericytes in these tissues. As we all know, pericyte in the tissue
448 have some stem cell characteristics and can differentiate into fibroblasts, and
449 chondrocytes(Armulik, Genové, & Betsholtz, 2011; Smyth et al., 2018). Pericyte 1
450 highly expressed stem cell related genes MCAM, MUSTN1 and have the
451 characteristics of myofibroblasts and pericyte 2 tend to have the characteristics of
452 fibroblasts. Pericyte 1 was increased and pericyte 2 decreased in the degenerated
453 group, which may change the properties of ligamental cells and contribute to the
454 ligamental degeneration.

455 Cells can communicate via ligand-receptor interactions(Kumar et al., 2018), so
456 targeting cell-cell interactions is frequently utilized in the clinical treatment. The
457 results of CellphoneDB analysis demonstrated that the high content of fibroblasts and
458 immune cells in the degenerative group had significantly higher interaction intensity,
459 such as fibroblast 1,2, and 8, which means that the interaction between cells in the
460 ligament was enhanced in the degenerative state. To identify the key factors regulating
461 the disease process, CellChat analysis was used to dissect the intercellular crosstalk

462 based on the signaling network in the human ACL. We found that FGF signaling
463 pathway and TGF- β signaling pathway were involved in the crosstalk network.
464 TGF β 1, contributes to osteophyte formation by inducing endochondral ossification, is
465 thought to be closely related to the onset of OA(Murata et al., 2019) and can be used
466 to induce chondrogenic differentiation of ligament-derived stem cells in
467 vitro(Schwarz et al., 2019). It has been reported that in myocardial fibrosis, liver
468 fibrosis, glaucoma and other diseases, TGF- β signaling pathway is also involved in
469 angiogenesis, ECM remodeling, pathological scar healing(Ilieş et al., 2021; Lee &
470 Massagué, 2022; P et al., 2018; Penn, Grobbelaar, & Rolfe, 2012). FGFs can induce
471 the fibroblast to myofibroblast differentiation, promote tissue repair by regulating cell
472 proliferation, survival and angiogenesis and contribute to ECM remodeling(Kendall &
473 Feghali-Bostwick, 2014; Ma, Iyer, Jung, Czubryt, & Lindsey, 2017). ECM
474 remodeling by overexpression, degradation and cross-linking of ECM proteins in the
475 lesioned tissue are direct factors leading to fibrosis tissues(Sun et al., 2022). In this
476 study, we observed that fibroblast9, inflammation related fibroblast, highly expressed
477 FGF7 and can act on FGFR1 mainly distributed in the fibroblast subgroups. Immune
478 cells especially macrophages highly expressed TGFB1 and can act on TGFBR1 and
479 TGFBR2 mainly distributed in the fibroblast and endothelial subgroups. These
480 findings suggested that FGF and TGF- β signaling pathways may induce ECM
481 remodeling in the process of ligamental degeneration and FGF7-FGFR1 and
482 TGFB1-TGFBR2 may be potential targets for the treatment of this disease.
483 SpRNA-seq was used to detect the spatial information underlying the normal and

484 degenerated ligaments and validate the findings acquiring from the ScRNA-seq.
485 Through the results, we observed that the disease group specific fibroblasts and
486 immune cells recognized by single cells were more numerous and more widely
487 distributed in the disease group specimens. We also get some spatial information, that
488 fibroblasts in the disease group were spatially closer to immune and endothelial cells,
489 which was more conducive to cell interaction.

490

491 **Conclusions**

492 In conclusion, our study described the cell atlas of the human ligament, providing a
493 valuable resource for further investigate of ACL homeostasis and the pathogenesis of
494 ligamental degeneration. The cellular heterogeneity and signaling network we
495 uncovered help to increase the understanding of the human ACL at a single-cell level
496 and provide crucial clues for establishing new diagnostic and therapeutic strategies for
497 this disease in the future.

499 **Declarations**

500 **Ethics approval and consent to participate**

501 This study was reviewed and approved by our University Ethics Committee (Ethics
502 Committee on Biomedical Research, West China Hospital of Sichuan University No.
503 658 2020-(921)) and all procedures complied with the Helsinki Declaration.
504 Participants gave informed consent to participate in the study.

505 **Consent for publication**

506 Not applicable.

507 **Conflict of interests**

508 The authors declared that they have no competing interests.

509 **Availability of data and materials:**

510 Data are available in a public, open-access repository. The single-cell RNA-seq data
511 and cluster annotations are available at GSA for human
512 (<https://ngdc.cncb.ac.cn/gsa-human/>) with the accession number PRJCA014157.

513 **Competing interests:**

514 The authors declared that they have no competing interests.

515 **Author's Contributions:**

516 WF and JL conceived the project. WF and JL designed the experiments. WF, RY and
517 MG collected the specimens. RY, TX, LZ and LY performed bioinformatic and
518 statistical analyses. WF and RY wrote the manuscripts. All authors commented and
519 revised the manuscripts.

520 **Acknowledgements:**

521 We appreciate all patients who participated in this study.
