1 Abstract (242/250)

2 Purpose:

3 Measures to control COVID-19 reduced face-to-face appointments and walk-ins at
4 sexual health services (SHSs). Remote access to SHSs through online self-sampling
5 for STIs was increased. This analysis assesses how these changes affected service
6 use and STI testing among young people in England.

7 Methods:

8 Data on all chlamydia, gonorrhoea and syphilis tests from 2019-2020 amongst
9 English-resident 15-24 year olds (hereafter referred to as 'young people') were
10 obtained from national STI surveillance datasets. We calculated proportional
11 differences in tests and diagnoses for each STI, by demographic characteristics
12 including age and socioeconomic deprivation, between 2019 and 2020. Among
13 those tested for chlamydia, we used binary logistic regression to determine crude
14 and adjusted odds ratios (OR) between demographic characteristics and being
15 tested for chlamydia by an online service.

16 Results:

17 Compared to 2019, there were declines in testing (30% for chlamydia, 26% for
18 gonorrhoea, 36% for syphilis) and diagnoses (31% for chlamydia, 25% for
19 gonorrhoea and 23% for syphilis) among young people in 2020. These reductions
20 were greater amongst 15-19 year-olds (vs. 20-24 year-olds). Among young people
21 tested for chlamydia, those living in the least deprived areas were more likely to be
22 tested using an online self-sampling kit compared to those living in the most deprived
23 areas (males; OR=1.24[1.22-1.26], females; OR=1.28[1.27-1.30]).

24 Conclusion:

1 The first year of the COVID-19 pandemic in England saw declines in STI testing and
2 diagnoses in young people and disparities in the use of online chlamydia self-
3 sampling which risk widening existing health inequalities.

6 *provision*

7

8 Implications and contributions (49/50)

9 There was a decrease in STI testing of young people during the first year of the
10 COVID-19 pandemic in England with larger reductions among teenagers. There was
11 an increase in use of online STI self-sampling services but with inequalities in
12 provision which risk widening existing inequalities in sexual health.

2

3 Background

4 Sexually transmitted infections (STIs) present a public health challenge in England.

5 The burden of STIs is greatest amongst young people aged 16-24 years and they

6 are most likely to access sexual health services (SHSs) ^[2-6]. Between 2010-12, they

7 had the highest prevalence of chlamydia (3.1% of women and 2.3% of men in this

8 age group). The prevalence of gonorrhoea was highest amongst people 20-24 years

9 of age^[7].

10 The majority of chlamydia and gonorrhoea infections are asymptomatic, particularly

11 amongst women, and may result in poor sexual and reproductive health if left

12 untreated^[8]; this includes a higher risk of pelvic inflammatory disease (PID), and

13 ectopic pregnancy, which are preventable with early diagnosis and treatment^[9, 10].

14 Consequently, opportunistic chlamydia screening has been offered to sexually active

15 15-24 year olds in England since 2003 through the National Chlamydia Screening

16 Programme (NCSP).

17 There have been increases in attendances at SHSs between 2016-2020^[3]. However,

18 SHS delivery was greatly disrupted in March 2020 after the introduction of public

19 health measures to reduce COVID-19 transmission such as national lockdowns, the

20 requirement to stay at home, and social distancing. Moreover, the introduction of

21 legislation restricting social interaction may have resulted in some people with STI-

22 related symptoms avoiding attending SHSs due to fear of being judged for breaking

23 these rules, creating a false sense of reduced demand on STI testing services^[11].

24 However, to ensure continued provision of STI testing, SHSs across England were

25 rapidly reconfigured to provide more remote care via online consultations^[3].

1 To understand how STI testing, diagnoses and service use among 15-24 year olds in
2 England changed during the first year of the COVID-19 pandemic, we compared the
3 demographic characteristics of young people tested for STIs in 2019 and 2020 then,
4 among all young people tested for chlamydia, determined the correlates of being
5 tested via an online service instead of a face to face appointment.

6 Methods

7 Data description

8 We conducted a retrospective cohort study of 15-24 year olds (hereafter referred to
9 as ‘young people’) residing in England who received an STI test or diagnosis utilising
10 data from the GUMCAD STI Surveillance System and the CTAD Chlamydia
11 Surveillance System. GUMCAD is a pseudonymised and depersonalised dataset of
12 all attendances at SHSs in England and was used to obtain data on chlamydia,
13 gonorrhoea and syphilis tests and diagnoses in young people attending this setting;
14 syphilis diagnoses included primary, secondary and early latent stages^[12, 13]. CTAD
15 is a pseudonymised and depersonalised dataset of all publicly provided chlamydia
16 tests and diagnoses, including those made through the NCSP, and was the source
17 of data for chlamydia tests and diagnoses from community-based settings (those
18 offering non-specialist STI-related care such as general practices and
19 pharmacies)^[14, 15]. All tests and diagnoses are coded by healthcare practitioners in
20 keeping with surveillance reporting specifications. To avoid double counting of tests
21 or diagnoses in each surveillance system, only one test or diagnosis of each STI for
22 each person with a unique person identifier was counted within a 6-week episode^[15].
23 Neither GUMCAD nor CTAD include personal identifiers so individuals cannot be
24 matched between datasets; individuals are identified using a clinic-specific patient
25 identification code in GUMCAD^[16] and a unique patient identifier number in CTAD^[14].

1 The study period was from 1st January 2019 to 31st December 2020 (inclusive),
2 where data from 2019 relates to the pre-COVID period and 2020 relates to the first
3 year of the COVID-19 pandemic. To be considered in the analysis data were
4 restricted to people aged 15-24 years, at the time of the test or diagnosis, residing in
5 England. Residential location was defined using the lower super output area (LSOA),
6 small geographical areas for the reporting of small area statistics with an average
7 size of 1,620 residents^[17]. To obtain a measure of area-level socioeconomic
8 deprivation, LSOAs were used to match to quintiles of the 2019 Index of Multiple
9 Deprivation (IMD) dataset^[18]. Additionally, the LSOAs were matched to the 2011
10 census area classification to categorise young people as living either in an urban or
11 rural setting ^[19-21]. Ethnicity was categorised using the national Census classification,
12 as follows: Asian (including Bangladeshi, Chinese, Indian, Pakistani and any other
13 Asian background), Black African, Black Caribbean, Other Black ethnicity, Mixed
14 ethnicity (including White and Black Caribbean, White and Black African, White and
15 Asian and any other Mixed or Multiple ethnic background), Other, and White^[22].

16 Statistical analysis

17 We determined the proportional change in the characteristics of young people tested
18 for STIs between 2019 and 2020. Demographic and clinical characteristics included
19 age group (15-19 or 20-24 years), area of residence (rural or urban), residential
20 area-level deprivation, (as defined by IMD quintile, where quintile 1 is the most
21 deprived and quintile 5 is the least deprived), ethnicity, gender and public health
22 region of residence (categorised as: East Midlands, East of England, London, North-
23 East, North-West, South-East, South-West, West Midlands and Yorkshire and
24 Humber) these characteristics were compared for all three STIs as they can be
25 assessed in both CTAD and GUMCAD surveillance systems. Sexual orientation

1 (including heterosexual males, men who have sex with men [MSM], heterosexual
2 females and women who have sex with women [WSW]), and HIV status (categorised
3 as; HIV diagnosed, HIV undiagnosed or unknown) were compared for gonorrhoea
4 and syphilis as they are only collected in the GUMCAD surveillance system. Testing
5 services (categorised as physical or online services) were compared for chlamydia
6 only, as the CTAD surveillance system comprehensively captures all chlamydia
7 testing from all publicly-commissioned testing services. The Pearson's chi-square
8 test was used to compare these characteristics across both years.

9 Subsequently, to assess any inequalities in the access to online self-sampling
10 services for chlamydia testing (hereafter: 'online chlamydia testing'), we restricted
11 the sample to young people tested for chlamydia then used binary logistic regression
12 to determine the crude and adjusted associations with being tested via an online
13 service (yes vs. no); all models were stratified by gender. Bivariate models were
14 created to determine the unadjusted odds ratios (ORs) for being tested online and
15 residential area-level deprivation, as defined by IMD quintile (the primary
16 independent variable), and each potential confounder (year of test, age group, area
17 of residence and region of residence). All associations with a p-value less than 0.05
18 were considered to be statistically significant and all variables that had significant
19 crude associations were included in the multivariable model. Adjusted odds ratios
20 (aORs) were calculated using hierarchical modelling and covariates were added
21 using a forward building approach. Firstly, Model 1 was constructed with year of test
22 included a priori due to the scale up of online service provision during 2020^[3]. The
23 remaining covariates were added sequentially as follows: Model 2 was based on
24 Model 1 with age group included as a confounder. Model 3 was based on Model 2
25 with the addition of area of residence. Lastly, Model 4 comprised Model 3 with the

1 inclusion of region of residence. Ethnicity was excluded from the regression analysis
2 due to a high degree of item non-response: 29% of young people tested for
3 chlamydia were reported with an unspecified ethnic group in CTAD. All data
4 analyses were performed using version Stata v15 (College Station, TX, USA)^[23].

5 Results

6 Trends in STI tests and diagnoses

7 There were 26-36% decreases in tests and diagnoses for chlamydia, gonorrhoea
8 and syphilis among young people between 2019 and 2020 (Tables 1-3). However,
9 there were greater proportional decreases among 15-19 compared to 20-24 year
10 olds. By ethnicity, testing and diagnoses of all 3 STIs decreased for all ethnic groups
11 with larger proportional declines among young people of Asian and Black non-
12 African/non-Caribbean ethnicities. The number of chlamydia tests fell across all the
13 different types of services offering testing (47%; 1,041,553 to 554,299), with the
14 exception of online services where there was a 33% increase in testing between
15 2019 (271,684 tests) and 2020 (361,622 tests). Comparisons by sexual orientation
16 could only be done for gonorrhoea and syphilis and, in both cases, testing and
17 diagnoses fell to the largest extent (33-46%) among heterosexual men.

18 Correlates of being tested for chlamydia via an online service

19 Amongst all young people tested for chlamydia, those living in the least deprived
20 areas were more likely to be tested online (unadjusted odds ratios - males: 1.24
21 [1.22-1.26]; females: 1.28 [1.27-1.30]) compared to young people living in the most
22 deprived areas. This association remained after adjusting for confounders in the final
23 model (males: 1.29 [1.27-1.32]; females 1.32 [1.30-1.34]) (Table 4). In the final
24 model, there was a greater likelihood of being tested for chlamydia via an online

1 service in 2020 [(males: 2.81 [2.77-2.84]; females: 2.45 [2.44-2.47]) vs. 2019] and a
2 similarly increased likelihood amongst 20-24 year olds [(males: 1.47 [1.45-1.49];
3 females: 1.63 [1.61-1.64]) vs 15-19 year olds]. Online testing was also more likely
4 among residents of urban areas [(males: 1.17 [1.15-1.20]; females: 1.16 [1.15-1.17])
5 vs rural] and was generally less likely among all regions of residence compared to
6 London (*Appendix B*).

1 Discussion

2 There was a decrease in STI testing and diagnoses among young people during the
3 first year of the COVID-19 pandemic, with up to 50% larger decreases in teenagers.

4 In keeping with the reconfiguration of SHSs in 2020 to offer more remote
5 consultations, we found a 33% increase in chlamydia testing of young people via
6 online services, but there was evidence of inequalities in access to testing via this
7 modality.

8 Among young people tested for chlamydia, those living in the least deprived areas
9 were more likely to be tested for chlamydia online, compared to those living in the
10 most deprived areas. Further inequalities in chlamydia online testing were found,
11 with young people living in rural areas or regions outside London and those aged 15-
12 19 being less likely to be tested for chlamydia using an online service. This suggests
13 that there may be socioeconomic or structural barriers to online testing, which may
14 include lack of online access. 15-19 year olds may find it more difficult to be tested
15 for chlamydia using an online service if they are still living with their parents and are
16 unable to discreetly receive the self-sampling kit. The greater likelihood of being
17 tested for chlamydia online for young people living in London reflects the fact that
18 there is a pan-London online sexual health service for all London residents^[24].

19 The reductions in STI testing between 2019 and 2020 are partly due to the extensive
20 public health measures to help reduce the transmission of COVID-19^[25]. Moreover,
21 individuals may have delayed their visits to SHSs due to fear of COVID infection^[26]
22 and with lockdown restrictions it would have been difficult to meet and interact with
23 new people, reducing the possibility of new sexual encounters^[26]. All these factors
24 may have contributed to the decline in STI testing in 2020.

1 Our findings are consistent with international literature highlighting the negative
2 impact the COVID-19 pandemic had on STI testing. A report from the EuroTEST
3 COVID-19 impact assessment consortium found that, among 34 countries in the
4 World Health Organization European Region and in different test settings, 95% of
5 them tested less than half the expected number of people between March and May
6 2020, this decline continued until August 2020^[27]. Research in the USA found a
7 reduction in STI testing and case detection resulting in more than, 27,000 missed
8 cases of chlamydia and 5,500 cases of gonorrhoea between March and June
9 2020^[25]. The implications of these missed cases are likely to be increased
10 community transmission due to the asymptomatic nature of these STIs and
11 associated long-term sexual and reproductive health complications^[25]. Studies have
12 found that testing via online services is preferred over physical services, particularly
13 amongst young people^[28], but this may not be the case for teenagers who are living
14 at home. The advantages of online services include privacy and the ability to self-
15 sample^[29]. Previous research has found that online testing is more likely to be used
16 by women and those between the ages of 20-30 compared to younger age groups.
17 Consistent with our findings, research conducted amongst online services and SHSs
18 in London found those living in less deprived areas are more likely to use online
19 services when testing for an STI even when adjusting for confounders^[30].

20 Our analysis benefitted from a very large sample from national surveillance datasets
21 which included patient-level data with key demographic factors so we could robustly
22 assess differences in testing patterns within different subgroups. However, our
23 analysis is not without limitations. Urban and rural area classifications were based on
24 the 2011 census (the most up to date dataset at the time of writing) and these may
25 not be accurate for all areas of England in 2020. We were unable to adjust for

1 ethnicity in the regression analysis predicting being tested online for chlamydia due
2 to a high proportion of missing values for ethnicity in the CTAD surveillance system.
3 The regression analysis was restricted to chlamydia because we were only able to
4 reliably identify all sources of online testing for chlamydia by using a combination of
5 CTAD and GUMCAD data at the time of writing. While GUMCAD is a rich source of
6 data on STI testing, it underestimates online testing for gonorrhoea and syphilis as it
7 could only identify online testing by standalone online providers, and not online
8 testing provided as an alternate service by physical SHSs, in 2019 and 2020.
9 Similarly, we did not perform a regression analysis with count data to determine
10 correlates of being tested for chlamydia online vs not being tested – this is because
11 of a lack of underlying population data for all key variables (e.g. age-group, gender
12 and residential area-level deprivation). However, as we have comprehensive data on
13 all young people tested for chlamydia, we were able to assess the correlates of
14 being tested online. Whilst we included deprivation quintile in our analyses, this in an
15 area-level, rather than individual-level, measure of deprivation and is subject to the
16 ecologic fallacy. Additionally, the larger proportional drop in STI tests among
17 teenagers may be explained by residual confounding as our analyses could not take
18 risk behaviours such as multiple condomless sex partners into account, and it is
19 unclear how this varied between 15-19 and 20-24 year olds between 2019 and 2020.
20 Reduced testing, missed infections and late diagnoses may have potential
21 consequences such as the increase in PID and infertility^[31]. This will impact the
22 quality of life of young people with STIs and increase costs to the healthcare system
23 with the need for treatments for STI-related complications or sequelae. Additionally,
24 the difference in the means of testing between those in the least and most deprived
25 areas suggests barriers to access to online services, which should not occur, as STI

- 1 testing is free at the point of delivery in England. Given the increasing shift to online
- 2 service provision, there remains a need to assess how equitably they are provided
- 3 and to reduce the risk of differential access widening existing inequalities in sexual
- 4 health.
