25 Abstract

Background: Hospital segregation by race, ethnicity, and health insurance coverage is prevalent, with
some hospitals providing a disproportionate share of undercompensated care. We assessed whether New
York City (NYC) hospitals serving a higher proportion of Medicaid and uninsured patients pre-pandemic
experienced greater critical care strain during the first wave of the COVID-19 pandemic, and whether this
greater strain was associated with higher rates of in-hospital mortality.
Methods: In a retrospective analysis of all-payer NYC hospital discharge data, we examined changes in

33 admissions, stratified by use of intensive care unit (ICU), from the baseline period in early 2020 to the

34 first COVID-19 wave across hospital quartiles (265,329 admissions), and crude and age-adjusted

inpatient mortality rates, also stratified by ICU use, in the first COVID wave across hospital quartiles

36 (23,032 inpatient deaths), based on the proportion of Medicaid or uninsured admissions from 2017-2019

37 (quartile 1 lowest to 4 highest). Logistic regressions were used to assess the cross-sectional association

between ICU strain, defined as ICU volume in excess of the baseline average, and patient-level

39 mortality.

40

Results: ICU admissions in the first COVID-19 wave were 84%, 97%, 108%, and 123% of the baseline 41 levels by hospital quartile 1-4, respectively. The risk-adjusted mortality rates for ICU admissions were 42 43 36.4 (CI=34.7,38.2), 43.6 (CI=41.5,45.8), 45.9 (CI=43.8,48.1), and 45.7 (CI=43.6,48.0) per 100 admissions, and those for non-ICU admissions were 8.6 (CI=8.3,9.0), 10.9 (CI=10.6,11.3), 12.6 44 45 (CI=12.1,13.0), and 12.1 (CI=11.6,12.7) per 100 admissions by hospital quartile 1-4, respectively. 46 Compared with the reference group of 100% or less of the baseline weekly average, ICU admissions on a 47 day for which the ICU volume was 101-150%, 151-200%, and > 200% of the baseline weekly average had odds ratios of 1.17 (95% CI=1.10, 1.26), 2.63 (95% CI=2.31, 3.00), and 3.26 (95% CI=2.82, 3.78) for 48 49 inpatient mortality, and non-ICU admissions on a day for which the ICU volume was 101-150%, 151-

50	200%, and > 200% of the baseline weekly average had odds ratios of 1.28 (95% CI=1.22, 1.34), 2.60
51	(95% CI=2.40, 2.82), and 3.44 (95% CI=3.11, 3.63) for inpatient mortality.
52	
53	Conclusions: Our findings are consistent with hospital segregation as a potential driver of COVID-related
54	mortality inequities and highlight the need to desegregate health care to address structural racism,
55	advance health equity, and improve pandemic resiliency.

71 Introduction

The COVID-19 pandemic has amplified long-standing health inequities in the US.¹⁻³ In New York City (NYC), the epicenter in the early phase of the pandemic, the inequitable impact of COVID-19 was particularly salient, as persons and communities who historically bear the greatest harms of structural racism and those suffering higher rates of poverty experienced disproportionate rates of COVID-19 infection, hospitalization, and mortality.⁴⁻⁶

77 Numerous studies have examined factors related to the inequitable impact of COVID-19.⁷⁻¹¹ One

78 potential, and under-studied, phenomenon is de facto hospital segregation (henceforth "hospital

referring to persistence of segregation by health insurance coverage, race, ethnicity,

80 language, and immigration status not sanctioned by law. Hospital segregation has been well documented

81 in NYC and has, among other consequences, contributed to wide inequities in resources for "safety net

82 hospitals", typically referring to hospitals that provide significant proportions of care for underinsured and

83 other vulnerable patients.¹²⁻¹⁵ For examples, studies have found that public and other safety-net hospitals

84 provided for a disproportionate share of Medicaid and uninsured care while private academic medical

85 centers (AMCs),¹⁵ generally acknowledged as the most well-resourced hospitals in NYC, were much less

86 likely to admit Black and uninsured patients.^{13,15}

87 With people of color and Medicaid-insured and uninsured individuals disproportionately served by the 88 safety-net system, a greater likelihood of exposure to and development of severe illness from COVID-19 89 infections among these populations may have led to a surge in the volume of patients needing critical care and straining of the intensive care unit (ICU) capacity among safety-net hospitals.¹⁶⁻²⁰ While some safety-90 91 net hospitals were able to increase ICU-capable beds as a response to surges in ICU demand, it was considerably more challenging to provide and train sufficient staff for ICU care.²⁰ Moreover, hospitals, 92 93 especially those that were not part of a larger system, faced additional constraints in their ability to load balance to other hospitals, leaving patients to receive care in overloaded ICUs or experience delays in 94

95	admission. ^{16,21} With safety-net providers being chronically underresourced, ^{22,23} this additional strain on
96	their already stretched-thin capacity may have resulted in higher in-hospital mortality. ¹⁷

97 Studies of hospital outcomes in NYC during the COVID-19 pandemic are mostly based on data or reports from individual hospitals or networks.^{16-21,24} Here, we used all-payer NYC hospital discharge data to 98 provide a population-level analysis across all hospitals to gain a full picture of the crisis citywide and to 99 100 assess disparities in outcomes in a segregated system of care. Specifically, we examined whether hospitals 101 serving a higher proportion of Medicaid and uninsured patients pre-COVID pandemic experienced larger 102 increases in inpatient use and greater rates of in-hospital mortality, stratified by ICU use, during the first 103 wave of the COVID-19 pandemic than hospitals serving a lower proportion of Medicaid and uninsured 104 patients pre-COVID pandemic. Additionally, we developed measures of ICU strain and formally assessed whether any excess in-hospital mortality risk was associated with strained ICUs.^{25, 26} Due to care 105 106 segregation and a greater likelihood of COVID-19 infection and hospitalization among Medicaid-insured 107 and uninsured individuals, we hypothesized that (1) hospitals serving a higher proportion of Medicaid and 108 uninsured patients pre-COVID experienced a greater surge of patients requiring critical care and higher 109 mortality rates during the first COVID-19 wave, and (2) the greater surge in critical care patients was 110 positively associated with patient mortality.

111

112 Methods

113 This retrospective study was approved by the NYC Department of Health and Mental Hygiene (DOHMH)

institutional review board as non-human subject research. There was no funding source for this study.

115 Data and Sample

116 Data on hospital outcomes in NYC were obtained from the Statewide Planning and Research Cooperative

117 System (SPARCS), a comprehensive all-payer data reporting system that collects information on

discharges from all Article 28 hospitals in New York State (federal, psychiatric, and long-term care

119	hospitals are excluded). Each discharge record in SPARCS includes information on patient demographics,
120	diagnoses, procedures, sources of payment, charges, and provider and hospital characteristics. Inpatient
121	records from NYC hospitals among individuals aged 18 and older were extracted for all of 2017-2019
122	(N=2,435,063) and for January 5-May 9 in 2020 (N=265,329). Geocoded 2020 SPARCS records were
123	linked to publicly available NYC nursing home addresses using the building identification number to
124	determine if a discharge was attributable to a nursing home resident.
125	The dates for accessing data used in this analysis spanned from November 2022 to June 2023. The
126	authors had access to information in SPARCS that could identify individual records.
127	Measures
128	Hospital segregation
129	We used 2017-2019 SPARCS data to characterize the extent of pre-existing hospital segregation by health
130	insurance coverage, which correlates highly with race/ethnicity. We ranked hospitals by the proportion of
131	all-cause adult hospitalizations for which the primary payer was Medicaid or self-pay in 2017-2019 and
132	grouped these hospitals into quartiles, with quartile 1 (Q1) including hospitals with the lowest proportions
133	of Medicaid or self-pay admissions, and quartile 4 (Q4) hospitals with the highest proportions of
134	Medicaid or self-pay admissions. Along with Medicaid insured admissions, we focused on self-pay
135	admissions since self-pay patients as a group had the highest concentration of care received from public
136	and private independent hospitals (> 65% in 2017-2019 SPARCS, data not shown), suggesting limited
137	access to well-resourced facilities among this population. Hospitals with a high proportion of Medicaid or
138	self-pay admissions may be referred to as safety nets in the study. ²⁷
139	Hospitalizations
140	We assessed three sets of hospitalizations: all-cause hospitalizations, ICU hospitalizations, and non-ICU
141	hospitalizations. All-cause hospitalizations included all admissions to NYC hospitals among adults ages

142 18 and older. ICU admissions were identified based on a validated measure using revenue center codes

143 (RCCs).²⁸ Non-ICU admissions were defined as admissions without the RCCs for ICU use and may
144 include admissions with intermediate ICU use.

145 *Inpatient mortality*

146 We also assessed three sets of in-hospital deaths: deaths among all-cause hospitalizations, deaths among 147 ICU hospitalizations, and deaths among non-ICU hospitalizations. We identified in-hospital death as 148 disposition on discharge status of expired or discharged to hospice. Both crude and risk-adjusted rates of mortality were calculated for hospitals as a group in each quartile. Patient-level characteristics, including 149 150 sex, age, race/ethnicity, primary payer, comorbidity, admission from nursing home, emergency 151 admission, severity of illness, and principal diagnosis, were used in non-hierarchical logistic regression 152 models to derive predicted probabilities of in-patient death, which were incorporated in the risk-adjusted 153 mortality rate calculations. The clustered sandwich estimator was used to account for potentially correlated outcomes among admissions to the same hospital. After accounting for patient-level factors, 154 any differences in (risk-adjusted) mortality rates across hospitals may be attributable to hospital-level and 155

156 other factors.²⁹

157 Hospital strain

The primary measure of critical care strain on a given day was the total number of ICU admissions to the
hospital in the week leading up to that day as a percentage of the hospital's pre-pandemic baseline
(defined below) weekly average ICU admissions. This percentage was expressed as one of the following
categories: 0-100%, 101-150%, 151-200%, and > 200%.

162 <u>Statistical analysis</u>

We performed the following to test the hypothesis that hospitals serving a higher proportion of Medicaid and uninsured patients pre-COVID experienced a greater surge of patients during the first COVID-19 wave. First, we calculated the ratio of hospitalizations for each quartile of hospitals between the two periods in 2020: (1) the pre-pandemic baseline period spanning the dates of January 5-March 7 (CDC

167 weeks 2-10 of 2020), and (2) COVID-19 Wave 1 spanning the dates of March 8-May 9 (CDC weeks 11-168 19 of 2020), with the ratio = the number of hospitalizations in Wave 1/the number of hospitalization in the baseline. We focused on the first COVID-19 wave and a preceding period of similar length since 169 reports and studies suggest that hospital capacity in NYC was particularly strained in the first wave of the 170 pandemic due to a surge of critically ill patients.¹⁶⁻¹⁸ The standard errors and confidence intervals for the 171 ratios of hospitalizations between the two periods were approximated using Fieller's Theorem.³⁰ Second, 172 173 we used t-tests to assess whether the ratios of hospitalizations from higher hospital quartiles were larger 174 than the ratios from lower hospital quartiles (p < 0.05).

175 To test the hypothesis that hospitals serving a larger proportion of Medicaid and uninsured patients pre-

176 COVID experienced higher mortality rates during the first COVID-19 wave, we used t-tests to assess

177 whether crude and risk-adjusted mortality rates for higher quartile hospitals were larger than those for

lower quartile hospitals during the first COVID-19 wave (p < 0.05). Between these two measures of

179 mortality, risk-adjusted rates may be of greater relevance since it is necessary to account for differences in

180 patient characteristics across hospitals in assessing the possibility of heightened mortality rates resulting

181 from hospital-level factors such as constrained capacity.

In addition to performing statistical testing of differences across hospital quartiles for the entire first wave of COVID-19 and the preceding baseline, we calculated weekly admissions and weekly in-hospital deaths as percentages of baseline weekly averages and illustrated them graphically to discern the weeks in which there may be particularly large disparities in outcomes. We also provided information on the

186 characteristics of admissions and deaths from the baseline and Wave 1 for all hospital quartiles to better

understand distributions of COVID-19 related burdens among various demographic groups.

188 We used both the hierarchical logistic regression model with hospital random intercept and non-

189 hierarchical logistic regression model with hospital fixed effects to assess the association between

190 hospital strain and patient-level mortality in the ICU setting, in the non-ICU setting, and for all adult

admissions. In addition to ICU strain, the following patient-, neighborhood-, and hospital-level covariates

192 were included in the model: sex (female), age (18-39, 40-64, 65-79, 80 or older), race/ethnicity (Asian or 193 Pacific Islander, Black, Hispanic, White, and Other non-Hispanic), primary payer (Medicaid, Medicare, 194 private/commercial, self-pay, and other), weighted Elixhauser comorbidity index, admission from nursing 195 home, measures of patient acuity, including emergency admission and severity of illness (SOI) (SOI 196 present on admission is based on All Patient Refined Diagnosis Related Groups (APR-DRG) 197 classification and coded as 1=minor, 2=moderate, 3=major, and 4=extreme), and principal diagnosis 198 based on Clinical Classification Software Refined (CCSR) version 2021.1 (including COVID-19 199 identification based on ICD-10 code U.071 in effect April 1, 2020), neighborhood of residence (defined 200 as Neighborhood Tabulation Area), and hospital type (private AMC and affiliates, private other, and 201 public). 202 Several alternative proxies for hospital strain were used to assess sensitivity of regression estimates to 203 hospital strain measures, including (1) daily average adult admissions with ICU use over a 7-day period 204 leading to the date of admission as a percentage of certified ICU beds, (2) adult COVID-19 positive 205 admissions with ICU use over a 7-day period leading to the date of admission as a percentage of adult 206 admissions with ICU use, and (3) adult sepsis admissions over a 7-day period leading to the date of 207 admission in any setting as a percentage of pre-pandemic weekly average adult sepsis admissions. 208 Data preparation and analyses were performed in R version 4.2.3 and Stata version 16, respectively. 209 210 Results 211 Pre-existing segregation of care (2017-2019)

Table 1 shows the characteristics of admissions and hospitals across the four quartiles of hospitals in
2017-2019. After excluding specialty hospitals and hospitals without ICUs, a total of 47 hospitals in three
categories – private AMC and affiliates, private other, and public – were included for the study. Q1
hospitals, almost all of which were AMCs or AMC affiliates, accounted for the highest proportion of all

admissions in NYC at 33% (802,657/2,437,334). The proportion of admissions provided by each quartile

217 steadily declined to 19% (464,936/2,437,334) among Q4 hospitals, all of which were public or private 218 independent. Almost all public hospitals in NYC are part of the H+H system, which is run by the city and 219 a primary provider of care for Medicaid and uninsured patients. The proportion of admissions for which 220 the primary payer was Medicaid or self-pay varied substantially, from 22% in Q1 to 61% in Q4, 221 confirming a high degree of hospital segregation by insurance coverage in NYC. Provision of care for 222 Medicaid or self-pay admissions disproportionately fell on public and non-AMC affiliated private 223 hospitals (hospitals in Q3 and Q4). In addition to substantially higher proportions of Medicaid or self-pay 224 admissions, hospitals in the higher quartiles tended to have admissions through emergency department 225 (ED) visits and admissions associated with younger patients, Black or Hispanic patients, patients from 226 higher poverty neighborhoods, and patients who were NYC residents.

227 Admissions and in-hospital mortality (2020)

Table 2 shows the numbers of admissions in the pre-pandemic baseline period and during COVID-19

229 Wave 1 and the ratios of admissions between these two periods across the four quartiles of hospitals.

230 Compared with the baseline, the number of all-cause admissions citywide declined by 17% in Wave 1.

All-cause admissions by Q1-Q4 hospitals were 73%, 84%, 87%, and 97% of their baseline levels,

respectively (all four ratios are statistically different from one another). The citywide number of ICU

admissions remained virtually unchanged in Wave 1, but there was significant variation among hospitals

across quartiles, with ICU admissions in Q1-Q4 hospitals being 84%, 97%, 108%, and 123% of the

baseline levels, respectively (all four ratios are statistically different), consistent with the hypothesis that

236 hospitals serving a higher proportion of Medicaid and uninsured patients pre-COVID experienced a

237 greater surge of patients requiring critical care during the first COVID-19 wave.

Table 3 shows crude and risk-adjusted mortality rates in each period across the four hospital quartiles.

The citywide number of in-hospital deaths among all admissions rose dramatically from 4,885 to 18,147,

- resulting in an increased crude mortality rate from 3.4 to 15.1 per 100 admissions. While both the crude
- and risk-adjusted mortality rates for all admissions were similar across quartiles pre-pandemic, there were

242	large disparities in these rates in wave 1. The crude mortality rates for all admissions in wave 1 were
243	11.5 (95% confidence level (CI)=11.1, 11.8), 16.4 (CI=16.0,16.9), 18.9 (CI=18.4,19.4), and 14.7
244	(CI=14.2,15.1) per 100 admissions among Q1-Q4 hospitals, respective. After accounting for differences
245	in patient-level characteristics, the risk-adjusted rates for all admissions were higher among Q3 and Q4
246	hospitals, 17.1 (CI=16.6,17.6) and 16.8 (CI=16.3,17.3) per 100 admissions, respectively, than Q1 and Q2
247	hospitals, 12.4 (CI=12.0,12.8) and 14.9 (CI=14.5,15.3) per 100 admissions, respectively, consistent with
248	the hypothesis that hospitals serving a higher proportion of Medicaid and uninsured patients pre-COVID
249	experienced higher mortality rates during the first COVID-19 wave.
250	The city-wide crude rate of mortality for ICU admissions increased from 14 to 42.5 deaths per 100
251	admissions. Q1 hospitals had significantly lower crude and risk-adjusted mortality rates than hospitals in
252	the other quartiles. Specifically, the risk-adjusted mortality rate for Q1 hospitals was 36.4 (CI=34.7,38.2)
253	per 100 ICU admissions vs. 43.6 (CI=41.5.45.8), 45.9 (CI=43.8.48.1), and 45.7 (CI=43.6.48.0) per 100

254 ICU admissions for Q2-Q4 hospitals, respectively. As non-ICU admissions made up close to 90% of all

admissions in both periods, crude and risk-adjusted rates for non-ICU admissions had similar patterns asthe rates for all admissions.

As shown in Tables S1-6, Hispanic and NH Black patients accounted for most of the increases in ICU
demand and all three sets of deaths in the higher quartile hospitals.

Figures 1 shows that weekly ICU admissions to Q4 hospitals in late March were more than 175% of the

260 baseline weekly average, substantially larger than the increase in ICU admissions experienced by Q1

261 hospitals. Figure 2 shows that both weekly ICU and non-ICU mortality reached their peaks in early April,

approximately 800% and 2,500% of the baseline weekly averages among Q4 hospitals.

263 <u>Regression estimates</u>

264 The full hierarchical logistic regression estimates for the three sets of inpatient deaths are presented in

265 Table S7. The regression estimates show that being male and being older were risk factors for in-hospital

266	mortality. Compared with NH Whites, Other race/ethnicity had a higher likelihood of ICU mortality while
267	NH Blacks had a lower likelihood of non-ICU mortality. Compared with private insurance, the primary
268	payers of Medicaid, Medicare, and Other were associated with a higher likelihood of mortality for both
269	ICU and non-ICU admissions. ICU admissions from nursing homes were associated with a lower
270	likelihood of mortality, but non-ICU admissions from nursing homes were associated with a higher
271	likelihood of mortality. Having a higher Elixhauser comorbidity score and a major or extreme SOI were
272	risk factors for both ICU and non-ICU mortality. Finally, compared with admissions to private AMCs and
273	affiliates, those to non-AMC affiliated private hospitals (most of which are independent) were associated
274	with a higher likelihood of ICU and non-ICU mortality.
275	Table 4 shows that critical care strain, the primary variable of interest, was associated with a higher
276	likelihood of both ICU and non-ICU mortality. Compared with the reference group of 100% or less of the
277	baseline weekly average, ICU admissions on a day for which the ICU volume was 101-150%, 151-200%,
278	and $> 200\%$ of the baseline weekly average had odds ratios of 1.17 (CI=1.10,1.26), 2.63 (CI=2.31,3.00),
279	and 3.26 (CI=2.82,3.78) for inpatient mortality, and non-ICU admissions on a day for which the ICU
280	volume was 101-150%, 151-200%, and $> 200\%$ of the baseline weekly average had odds ratios of 1.28
281	(CI=1.22,1.34), 2.60 (CI=2.40,2.82), and 3.44 (CI=3.11,3.63) for inpatient mortality.
282	As shown in Tables S8-10, the regression estimates for hospital strain were similar with alternative strain
283	measures. Additionally, as reported in Table S11, the non-hierarchical logistic regression with hospital
284	fixed effects produced similar estimates for the hospital strain and other variables.
285	

- 286 Discussion
- 287 The COVID-19 pandemic had a devastating and inequitable impact on NYC.³¹ With three quarters of
- 288 COVID-19 related deaths in NYC taking place in hospitals, which have been found to be highly
- segregated, this study examined the possible relationship between hospital segregation and the high rates
- of in-hospital mortality in NYC using all-payer hospital discharge data. We found that hospitals serving a

high proportion of Medicaid or uninsured patients pre-COVID-19 pandemic experienced a greater strain
in ICU capacity and larger crude and risk-adjusted mortality rates for both ICU and non-ICU admissions
during the first wave of the pandemic. Additionally, we found that strained ICU capacity was
independently associated with a greater likelihood of in-hospital death. Together, these findings suggest
that a greater surge of patients needing critical care in segregated, under-resourced hospitals may have
contributed to excess mortality rates, with Hispanic and NH Black patients accounting for most of the
mortality increases.

Our study complements the existing literature in several ways. First, while strained critical care capacity 298 has been linked to greater in-hospital mortality in both the pandemic and non-pandemic settings,^{18,25,26,32} 299 300 relatively few studies have assessed differences in critical care strain and outcomes across a census of hospitals within the same jurisdiction. Second, with few exceptions,^{25,26} current studies on critical care 301 302 strain have generally not examined the impact of critical care strain on non-ICU patients. Consistent with an analysis conducted by Kadri et al.,²⁶ we found that strained ICU capacity may be associated with worse 303 304 outcomes among non-ICU patients, suggesting the importance of including both ICU and non-ICU 305 outcomes in assessing the impact of critical care strain. Third, a recent study found that load imbalance was widespread in the US during the COVID-19 pandemic.³³ Additionally, the study found that hospitals 306 307 serving high proportions of Medicaid patients and Black Medicare patients tended to be over capacity in regions experiencing load imbalance. Focusing on NYC, our study not only found similar results but 308 309 further demonstrated the potential adverse impact of load imbalance and critical care strain on health 310 outcomes. Finally, our study added to the accumulating body of evidence that segregation of care may lead to health disparities.^{14,34} 311

Structural racism in historical and modern health care policy has contributed to people of color being
disproportionately uninsured or covered by public insurance programs that offer lower reimbursement
rates, a key driver of health care segregation.³⁵ Other racist policies, such as redlining, a federal program
designed to residentially segregate Black and immigrant communities, also contributed to care

segregation.^{36,37} While a comprehensive discussion of potential policy solutions for care segregation is 316 317 beyond the scope of this paper, we offer the following recommendations. First, in order to incentivize providers to serve uninsured and Medicaid-insured patients, it is essential to institute payment reforms, 318 319 such as raising Medicaid reimbursement rates and implementing hospital price regulation, and to expand health insurance coverage.³⁸⁻⁴¹ Second, it is important to enforce tax-exempt status for non-profit hospitals 320 321 and ensure that benefits they provide for marginalized communities are commensurate to tax breaks and other government benefits received.⁴² Finally, measures that advance anti-racism in clinical practice and 322 care and policies that address broader social exclusion and residential segregation and promote 323 reinvestment in historically redlined neighborhoods and minority service institutions are needed.^{35,43,44} 324 325 Our study findings may also inform preparedness and response in future pandemics and other health care 326 emergencies. As all disease outbreaks are likely to have a disproportionate impact on marginalized populations,⁴⁵ persistence of care segregation would lead to overburdened safety-net hospitals and worse 327 328 outcomes in these facilities. Hence, it is crucial to strengthen support for the safety-net system and ensure 329 its ability to meet unexpected increases in demand for ICU and other services, including addressing shortages of specialized health care providers.²⁰ Development of coordinated regional plans for load 330 balancing is also necessary to promote equitable and timely access to critical care and prevent 331 332 catastrophic outcomes among overburdened safety-net facilities during times of crisis, with an emphasis 333 on supporting independent safety-net hospitals that may face additional hurdles in coordinating load balancing.46 334

335 Limitations

This study has several limitations. First, the discharge records included in SPARCS were provided by individual facilities, which may have inconsistent coding and reporting practices, resulting in issues such as misclassification of race/ethnicity that has been found to be more likely for Hispanic and Asian or Pacific Islander patients, potentially understating the impact of the pandemic on these groups in the analysis.⁴⁷ Second, our measures of hospital strain were imperfect proxies, as we did not have full

341 information on each hospital's capacity to provide critical care and the demand for their critical care 342 services. Third, the COVID-19 diagnosis code was not implemented until April 1, 2020; as a result, we could not identify many of the patients infected with COVID if they were discharged before that date. 343 344 Nonetheless, as shown in Table S12, we obtained similar estimates for hospital strain if only admissions 345 on or after April 1 were included in the model. Fourth, patients who died in a hospital before they could 346 be admitted were not included in the mortality analysis. Fifth, using the winter months of 2020, during 347 which there may already be a high number of respiratory-related hospitalizations, as the baseline period 348 could have underestimated the overall impact of COVID-19. Finally, while we accounted for many key 349 variables, the estimates for hospital strain may still be biased by unobserved factors.

350

351 Conclusions

352 Similar to many large cities in the US, NYC has a highly segregated healthcare system, with safety-net 353 hospitals providing a disproportionate share of care for low-income and racial/ethnic minority patients. 354 This population-level analysis of hospitalizations in NYC found that the greater strain in ICU capacity among safety-net hospitals was associated with higher likelihood of inpatient mortality during the first 355 wave of the COVID-19 pandemic. Our findings are consistent with the hypothesis that health care 356 357 segregation may have a substantial impact on health inequities and highlight the essential role of 358 desegregating health care, strengthening support for the safety-net system, and reinvesting in redlined 359 neighborhood during a pandemic and beyond in the promotion of health equity.

Abbreviations: NYC = New York City; NH = non-Hispanic; AMC = academic medical center (including affiliates).

^a Hospital quartiles are defined based on a hospital's percentage of adult hospitalizations where the primary payer was Medicaid or self-pay. Hierarchical algorithm based on common payment logic was used to identify primary payer.

^b Excludes specialty hospitals and hospitals without intensive care units (N = 6).

^c Poverty estimates may not be available for all NYC neighborhoods.

Table 2: Admissions and ratios of admissions among adults ages 18+ in NYC by hospita	l quartila January 5 May 0, 2020 ^a
Table 2. Admissions and fatios of admissions among addits ages 10+ in NTC by hospita	i qualuic, January J-May 9, 2020

Abbreviation: NYC = New York City; CI = 95% confidence interval; ICU = intensive care unit

^a Hospital quartiles are defined based on a hospital's 2017-2019 percentage of adult hospitalizations where the primary payer was Medicaid or self-pay.

Hierarchical algorithm based on common payment logic was used to identify primary payer.

^b Excludes specialty hospitals and hospitals without ICUs (N=6).

^c Pre-pandemic period is defined as CDC weeks 2-10 of 2020, corresponding to January 5-March 7, 2020 (based on date of admission).

^d Wave 1 of COVID-19 is defined as CDC weeks 11-19 of 2020, corresponding to March 8-May 9, 2020 (based on date of admission).

^e ICU use is defined based on revenue codes 200, 201, 202, 203, 204, 207, 208, 209, 210, 211, 212, 213 and 219 (Weissman et al. 2017).

^fNon-ICU use is defined as any admissions without revenue codes for ICU use but may include intermediate ICU use.

 g The ratio of admissions in each quartile is statistically different from the ratios of admissions in all other quartiles at p < 0.05.

Source: New York State Department of Health, Statewide Planning and Research Cooperative System (SPARCS) 2020 inpatient data, 2022 release.

Table 3: Crude and risk-adjusted mortality rates among adults ages 18+ in NYC by hospital quartile, January 5-May 9, 2020^a

Bolded number indicates that the mortality rate for a quartile is statistically different from the rates for all other quartiles in Wave 1 (p < 0.05).

Abbreviation: NYC = New York City; CI = 95% confidence interval; ICU = intensive care unit

^a Hospital quartiles are defined based on a hospital's 2017-2019 percentage of adult hospitalizations where the primary payer was Medicaid or self-pay.

Hierarchical algorithm based on common payment logic was used to identify primary payer.

^b Excludes specialty hospitals and hospitals without ICUs (N=6).

^c Pre-pandemic period is defined as CDC weeks 2-10 of 2020, corresponding to January 5-March 7, 2020 (based on date of admission).

^d Wave 1 of COVID-19 is defined as CDC weeks 11-19 of 2020, corresponding to March 8-May 9, 2020 (based on date of admission).

^e The following patient-level characteristics were used for risk adjustment: sex, age, race/ethnicity, primary payer, weighted Elixhauser comorbidity index, admission from nursing home, emergency admission, severity of illness, and principal diagnosis.

^f ICU use is defined based on revenue codes 200, 201, 202, 203,204, 207, 208, 209, 210, 211, 212, 213 and 219 (Weissman et al. 2017).

^g Non-ICU use is defined as any admissions without revenue codes for ICU use but may include intermediate ICU use.

Table 4: Independent association between hospital strain and inpatient mortality among adults (18+) in New York City, January 11- May 9, 2020^{a,b}

* p<0.05, ** p<0.01, *** p<0.001

Abbreviations: ICU = intensive care unit

 a < 100 observations were excluded due to missing data.

^b Estimates were generated from hierarchical logistical regressions, controlling for patient sex, age, race/ethnicity, primary payer, weighted Elixhauser comorbidity index, admission from nursing home, emergency admission, severity of illness (SOI), principal diagnosis, neighborhood of residence, and hospital type.

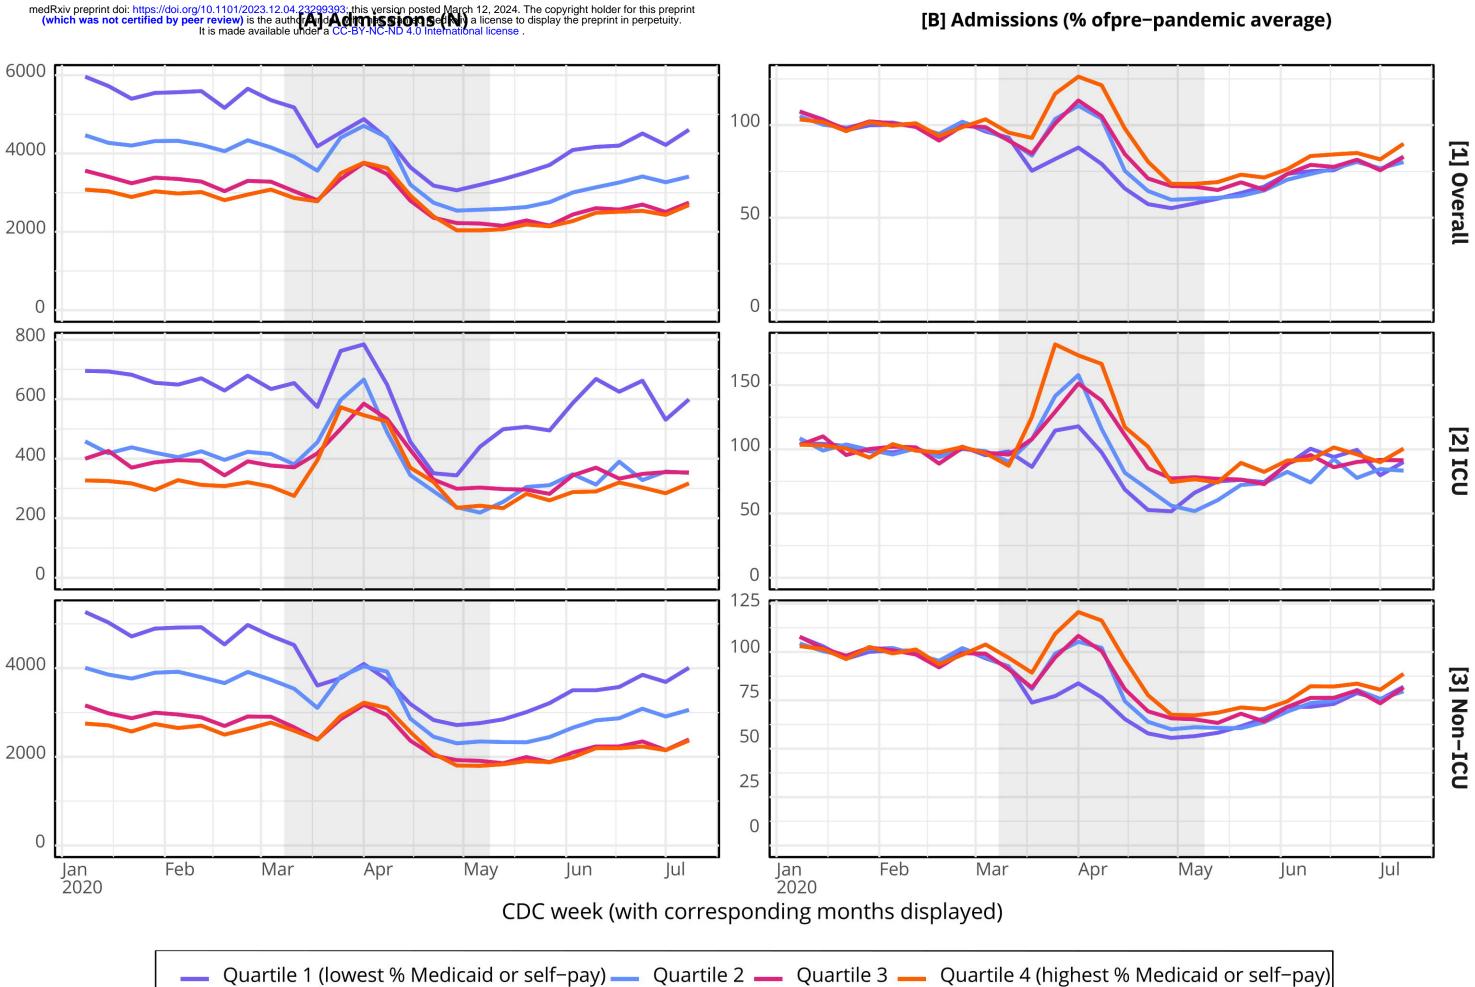

^c ICU use is identified based on revenue codes 200, 201, 202, 203,204, 207, 208, 209, 210, 211, 212, 213 and 219 (Weissman et al. 2017).

^d Non-ICU use is defined as any admissions without revenue codes for ICU use but may include intermediate ICU use.

^e Hospital strain is defined as the total number of adult ICU admissions to the hospital in the week prior to and including the patient admission date as a percentage of the hospital's pre-pandemic baseline weekly average ICU admissions.
