## 1 **Abstract**

2 **Background:** The aetiology of most childhood cancers is largely unknown. Spatially varying  
3 environmental factors such as traffic-related air pollution, background radiation and agricultural  
4 pesticides might contribute to the development of childhood cancer. We investigated the spatial  
5 variation of childhood cancers in Switzerland using exact geocodes of place of residence.

6 **Methods:** We included 5,947 children diagnosed with cancer during 1985-2015 at age 0-15 from the  
7 Swiss Childhood Cancer Registry. We modelled cancer risk using log-Gaussian Cox processes and  
8 indirect standardization to adjust for age and year of diagnosis. We examined whether the modelled  
9 spatial variation of risk can be explained by ambient air concentration of NO<sub>2</sub>, natural background  
10 radiation, area-based socio-economic position (SEP), linguistic region, years of existing general cancer  
11 registration in the canton or degree of urbanization.

12 **Results:** For all childhood cancers combined, the posterior median relative risk (RR), compared to the  
13 national level, varied by location from 0.83 to 1.13 (min to max). Corresponding ranges were 0.96 to  
14 1.09 for leukaemia, 0.90 to 1.13 for lymphoma, and 0.82 to 1.23 for CNS tumours. The covariates  
15 considered explained 72% of the observed spatial variation for all cancers, 81% for leukaemia, 82%  
16 for lymphoma and 64% for CNS tumours. There was evidence of an association of background  
17 radiation and SEP with incidence of CNS tumours, (1.19;0.98-1.40) and (1.6;1-1.13) respectively.

18 **Conclusion:** Of the investigated diagnostic groups, childhood CNS tumours show the largest spatial  
19 variation in Switzerland. The selected covariates only partially explained the observed variation of  
20 CNS tumours suggesting that other environmental factors also play a role.

## 1 **Introduction**

2 The causes of childhood cancers are poorly understood. Epidemiological research on the atomic bomb  
3 survivors indicated that ionising radiation in high doses can cause childhood leukaemia and central  
4 nervous system (CNS) tumours [1, 2]. A number of environmental factors have been suggested that  
5 could partially explain cancer risks in the general population, including traffic-related air pollution [3],  
6 background radiation [2, 4] and agricultural pesticides [5]. These risk factors vary in space and it is  
7 thus natural to expect spatial variation in childhood cancer incidence. Conversely, investigating the  
8 spatial variation of childhood cancer incidence might help generate new hypotheses about  
9 environmental risk and identify areas of potential environmental contamination.

10 Disease mapping, i.e. smoothing and visualising disease risk in space, is a common way of capturing  
11 the spatial variation of a disease. Several previous studies have investigated spatial variation in  
12 childhood cancer risk using disease mapping. Studies have focused on childhood leukaemia reported  
13 evidence of spatial variation in Ohio, Texas, Yorkshire [6-8], but not in France [9]. The study in Texas  
14 also examined childhood lymphomas and reported some evidence of spatial variation of Hodgkin  
15 lymphoma [7]. A study in Kenya reported evidence of spatial variation of Burkitt's lymphoma with  
16 higher rates in the northern part of the country [10]. A study in Florida focusing on childhood brain  
17 tumours reported some evidence of high excess risk in several non-adjacent counties [11].

18 The mixed results might reflect differences between the countries or methodological limitations. Most  
19 previous studies relied on areal data (data aggregated on administrative units) [7-9, 11-13]. Results  
20 from such studies depend on spatial unit selected, which is referred to as the Modifiable Areal Unit  
21 Problem [14]. Furthermore, associations between cancer incidence and environmental factors assessed  
22 at group level may be subject ecological fallacy, i.e. they may not correctly reflect underlying  
23 associations at the individual level [15]. The use of precise geocodes can overcome the  
24 aforementioned issues. In a simulation study, we showed that spatial modelling based on exact  
25 geocodes is more sensitive in identifying areas of higher risk compared to traditional disease mapping  
26 based on count data aggregated to small administrative areas [16]. To the best of our knowledge only  
27 one study in Ohio had available precise geocodes, but the authors did not attempt to explain the

1 observed variation of childhood leukaemia risk by incorporating environmental exposures in the  
2 model [6]. Lastly, all the previous studies used geographical information about the place of diagnosis  
3 only. Children may be more susceptible to certain environmental exposures early in life and thus  
4 location of residence at birth may be more relevant [17].

5 In this nationwide study, we investigated the spatial variation of childhood cancers using precise  
6 locations of residence. We performed analysis using place of birth and diagnosis. We focused on the  
7 following main diagnostic groups: all childhood cancers, childhood leukaemia, lymphoma and CNS  
8 tumours and assessed the extent to which selected covariates could explain the observed spatial  
9 variation.

## 10 **Methods**

### 11 **Study population**

12 We retrieved children diagnosed with cancer in Switzerland during 1985-2015 at age 0-15 from the  
13 Swiss Childhood Cancer Registry (SCCR). SCCR is a nationwide registry with high completeness.  
14 Estimates suggest that it includes 91% of all incident cases for the period 1985-2009 and >95% for  
15 1995-2009.[18] It collects residential addresses from time of diagnosis back to birth. The addresses  
16 were geocoded according to the Swiss grid coordinate system using a combination of different sources  
17 of georeferenced building addresses including the Swiss postal system, the geoportal maintained by  
18 the Federal Office of Topography and Google Maps.

19 Population data was available through the Swiss National Cohort (SNC) which includes geocoded  
20 residential locations of all Swiss residents at time of censuses (1990, 2000 and 2010-2015). To  
21 calculate population at risk by age group, year and spatial unit (1km grid cell or municipality), we  
22 performed linear interpolation of age, year and spatial unit specific weights, see Additional File Text  
23 S1 and Figures S1-2. We then performed indirect standardization by calculating the expected number  
24 of cases adjusted by age and year: Let  $q_{i,j}$  be the nationwide cancer incidence and  $P_{i,j,k}$  the  
25 population counts with subscript referring to the  $i$ -th age group (0-4, 5-9, 10-15),  $j$ -th year (1985-  
26 2015), and  $k$ -th spatial unit (grid cell, or municipality). Then the expected number of cases in the  $k$ -th  
27 spatial unit is:

1 
$$E_k = \sum_i \sum_j q_{i,j} \cdot P_{i,j,k}.$$

2 To calculate the expected number of cases for the analysis based on the location at birth we used a  
3 similar approach (Additional File Text S1).

#### 4 **Outcomes**

5 The SCCR classifies diagnoses according to the International Classification of Childhood Cancers  
6 Third Edition (ICCC3). We examined all childhood cancers combined (ICCC3 main groups I-XII) and  
7 then separately childhood leukaemia (ICCC3 main group I), lymphoma (ICCC3 main group II) and  
8 CNS tumours (ICCC3 main group III). We focused on the main diagnostic groups because of the  
9 larger sample size.

#### 10 **Covariates**

11 As potential explanatory variables, we included predicted ambient air concentration of NO<sub>2</sub>, predicted  
12 total dose rate from terrestrial gamma and cosmic radiation, neighbourhood-level socio-economic  
13 position (Swiss-SEP) [19], years of general cancer registration in the canton, language region and the  
14 degree of urbanisation as covariates (Table S1 and Figures S3-8 on the Additional File). Traffic-  
15 related air pollution and total background radiation were previously found to be associated with  
16 childhood cancer risks in Switzerland [20, 21]. We included SEP, linguistic region and degree of  
17 urbanisation to account for regional, socio-economic and socio-cultural differences. We included years  
18 of cantonal cancer registration to account for heterogeneous registry completeness. The SCCR records  
19 childhood cancer cases treated in one of the nine specialised paediatric oncology (SPOG) clinics and  
20 complements the registry with any additional cases recorded by the cantonal registries. Some cantons  
21 already had a cancer registry at the beginning of our study period, others established one during the  
22 study period and others after the end of the study. For cantons with more years of general registration,  
23 we thus expect the “apparent” childhood cancer incidence over the study period to be slightly higher.

#### 24 **Statistical Analysis**

25 We used log-Gaussian Cox processes (LGCPs) to model locations of incident cancer cases. A detailed  
26 description is provided in the Supplementary Text S2 [22]. Conditional on the risk surface, the point

1 process assumed to generate the case locations is an inhomogeneous Poisson process. We model the  
2 continuous log-risk surface via a spatial mixed effects model, adjusting for covariate effects. The  
3 spatial variation is modelled as a random process  $Z(s)$ , which is assumed to be a realization of a zero  
4 mean Gaussian random field with a Matérn covariance function and smoothness parameter  $\nu$  fixed to  
5 1. The Gaussian field is then defined by two parameters, a variance parameter  $\sigma^2$  and a range  
6 parameter  $\rho$  (a distance at which the correlation between two points of the field is approximately  
7 0.10). We fitted the model using the stochastic partial differential equation approach to approximate  
8 the continuous Gaussian field [23], and the Integrated Nested Laplace Approximation to perform  
9 accurate and computationally feasible Bayesian analysis [24, 25].

10 We computed maps of posterior median (unadjusted or adjusted for the covariates) of spatial relative  
11 risk (RR, i.e.  $\exp\{Z(s)\}$ ) compared to national level on a  $1 \times 1km^2$  grid. We also mapped exceedance  
12 probabilities defined as the posterior probability, in each grid cell, that RR exceeds 1. The fixed effects  
13  $\beta_i$  (log-relative-risk per unit increase in the covariate) are reported as posterior median of RR, i.e.  
14  $\exp\{\beta_i\}$ , and 95% credibility intervals (CI). The continuous variables NO<sub>2</sub>, ionizing radiation, SEP and  
15 years of cantonal cancer registration were scaled and thus  $\exp\{\beta_i\}$  is interpreted as the multiplicative  
16 change of the risk if at a fixed location when the covariate is increased by 1 standard deviation (SD).  
17 They were included as linear terms since there was no indication for a more complex model  
18 (Additional File Figure S9). Henceforth, the model adjusted for the aforementioned covariates is  
19 referred to as the adjusted model, whereas the model without covariates as the unadjusted. Both  
20 adjusted and unadjusted models are standardized for population, age and year of diagnosis by  
21 including the expected number of cases as an offset in the model (Additional File Text S1-2).

22 We also report the percentage of variance explained by the selected risk factors by evaluating median  
23 and 95% CI of the posterior of an extension of Bayesian  $R^2$  [26]:

24 
$$R^2 = \frac{V(\mathbf{X}(s)\boldsymbol{\beta})}{V(\mathbf{X}(s)\boldsymbol{\beta})+V(Z(s))},$$

25 where  $V(\cdot)$  denotes the variance over the  $K$  spatial units,  $\boldsymbol{\beta}$  is the vector of intercept and covariates and  
26  $\mathbf{X}(s)$  is the design matrix. We calculated  $R^2$  for the fully adjusted model, a model including all

1 selected covariates except years of cantonal cancer registration (we refer to this set of covariates as  
2 ‘putative risk factors’), and the univariable model including only years of cantonal cancer registration.  
3 This allows us to distinguish spatial variation explained purely by the degree of completeness of  
4 registration from variation explained by covariates that might reflect aetiological factors (putative risk  
5 factors). For consistency with the literature, we also fitted the Besag-York-Mollié (BYM) model using  
6 disease counts per municipality, for more information see [27-29] and Text S2 of the Additional File.

## 7 **Sensitivity Analysis**

8 We ran a sensitivity analysis to examine the robustness of the results with respect to different scalings  
9 of the penalized complexity priors for the range parameter of the latent field [28], with median range  
10 fixed at 1, 10, 60, 120 and 240km.

## 11 **Results**

### 12 **Study Population**

13 We identified 5,969 cases with childhood cancer during 1985-2015 in Switzerland. We excluded 22  
14 (0.3%) cases without available geocode of residence at diagnosis. Of the included 5,947 children, 32%  
15 (N = 1,880) had leukemia, 13% (N = 772) lymphoma and 22% (N = 1,290) a CNS tumor. For the  
16 analysis using location at birth we first excluded 1,194 cases born before 1985 and then 577 additional  
17 cases with no geocode at birth yielding 4,198 cases for the analysis (Table 1). Of the excluded cases  
18 for this analysis, 342 were born abroad, 114 were born in Switzerland but no address was recorded,  
19 while for 121 the country of birth was missing. The age and sex distribution follows similar patterns as  
20 in neighboring countries (Table 1) [30, 31].

### 21 **Spatial analysis**

22 We found evidence of spatial variation for all cancers combined and CNS tumours at diagnosis, Figure  
23 1, Table 2 and Table S2. For leukaemia and lymphoma the posterior median of the variance  
24 hyperparameter of the Gaussian field ( $\sigma^2$ ) was shrunk to 0 or values close to 0, indicating small, if  
25 any, spatial variation (Table 2 and S2).

1 For all cancers grouped together, the medians of the posterior distributions of RR evaluated at the  
2 centroids of  $1 \times 1\text{km}^2$  grid cells varied from 0.83 to 1.13 (min to max) throughout Switzerland,  
3 indicating at most a 13% increase in the risk in certain grid cells compared to Switzerland as a whole  
4 (Table 2 and Figure 1). The corresponding exceedance probability maps show areas, for which the  
5 posterior probability of having an RR greater than 1 is above 0.80 highlighted in light green or yellow  
6 (Figure 2). When we adjust for the selected covariates almost 72% (95% CI: 43%, 89%) of the  
7 observed variation was explained, with the median residual RR after adjustment varying from 0.86 to  
8 1.08 (min to max), Figure 1, Table 2. The putative risk factors explained 65% (35%, 86%) of the  
9 observed variation (Additional File, Table S3). In the fully adjusted model, the factors  $\text{NO}_2$  (RR 1.02;  
10 95% CI 0.99-1.06 per 1 SD increase in  $\text{NO}_2$ ), total background radiation (1.08; 0.99-1.18) and years of  
11 cantonal cancer registry (1.06; 1.03-1.09) were positively associated with cancer risk, whereas the  
12 association with the other covariates was weak (Figure 3 and Additional File Table S4).

13 Childhood leukaemia risks showed smaller spatial variation with the median posterior RR per grid cell  
14 varying from 0.96 to 1.09 on the unadjusted and from 0.97 to 1.04 on the fully adjusted model, Figure  
15 1 and Table 2. The proportion of spatial variation explained by the selected covariates was 81% (58%,  
16 94%), Table 2, whereas solely by the selected risk factor 64% (33%, 84%), Additional File, Table S3.  
17 In the fully adjusted model, the factors associated with the spatial risk of childhood leukaemia were  
18  $\text{NO}_2$  exposure (1.05; 0.99-1.11) and years of cantonal cancer registry (1.06; 1.01-1.11), Figure 3 and  
19 Additional File Table S4.

20 A small amount of spatial variation of RR was also observed for childhood lymphoma with the median  
21 RR varying from 0.90 to 1.13 on the unadjusted model and 0.96 to 1.07 on the adjusted model (Figure  
22 1 and Table 2). About 82% (60%, 94%) of the observed spatial variation in the risk could be  
23 explained with the selected covariates, most of it due to the putative risk factors (Additional File,  
24 Table S3). In the fully adjusted model, the factor contributing most was living in the French speaking  
25 part of Switzerland with a 1.18 (0.96, 1.44) RR increase compared to living in the German speaking  
26 part, Figure 3 and Additional File Table S4.

1 Among the investigated diagnostic groups, the greatest spatial variation of cancer risks was observed  
2 for childhood CNS tumours. The median posterior grid-specific RR varied from 0.82 to 1.23 before  
3 adjusting, and from 0.87 to 1.25 after adjusting for the selected covariates. These covariates explained  
4 64% (31%, 84%) of the observed spatial variation, and the putative risk factors alone 62% (28%,  
5 92%), Additional File, Table S3 and Table 2. Total background radiation exposure (1.17;0.98-1.4),  
6 SEP (1.06;1-1.13) and year of existing cantonal cancer registry (1.04;0.97-1.12) were positively  
7 associated with CNS tumour incidence. The association of the other covariates was weak, Figure 3 and  
8 Additional File Table S4.

9 We also examined the spatial variation of childhood cancers using place of birth. The spatial variation  
10 of cancer risks was generally smaller but the spatial patterns were largely consistent with the results  
11 for diagnosis (Additional File Figures S10-11 and Table S3 and S5).

12 We also examined the spatial variation using the BYM model. The maps and variation of median  
13 posterior RR were similar to the ones obtained by LGCPs, Additional File Figures S10-15. The  
14 estimates of the fixed effects were in the same direction but tended to be somewhat weaker than in the  
15 LGCP models (Additional File, Tables S4-7).

## 16 **Sensitivity analysis**

17 The resulting maps and effect estimates varied only little when using different priors for the  
18 hyperparameters, Additional File Figures S16-25.

## 19 **Post-hoc analysis**

20 Given the larger spatial variation in the risk of CNS tumours we ran several post-hoc analyses for this  
21 diagnostic group. First, we restricted the analysis to place of diagnosis for the period of 1995-2015 (n  
22 = 968), in which the coverage is highest (>95%). The resulting spatial pattern was closely similar to  
23 the main analysis (Figure S26). Second, we wanted to identify if the observed variation of CNS  
24 tumour was specific to particular diagnostic subgroups. We reran the analysis for place at diagnosis  
25 for astrocytoma (IIIb, n=511 cases), intracranial and intraspinal embryonal tumors (IIIc, n=266) and  
26 other CNS (IIIa, IIId-f, n=512), following the classification used in our previous analysis of spatial  
27 clustering of childhood cancers in Switzerland [16]. We found that intracranial and intraspinal

1 embryonal tumors showed the highest spatial variation with the median posteriors RR varying from  
2 0.74 to 1.59 (min to max) in the unadjusted and 0.74 to 1.38 in the adjusted model, Figure S27.  
3 However, the areas highlighted in Figures 1-2 stand out in all CNS subgroups Figures S27-28. Lastly,  
4 we hypothesized that differences in diagnostic practices between the nine SPOG clinics may explain  
5 the apparent spatial variation of CNS tumour risks. We thus constructed a spatial covariate reflecting  
6 the catchment areas of the different SPOG centres. Including an additional random effect to adjust for  
7 these catchment areas only slightly reduced the unexplained spatial variation. The spatial pattern of  
8 relative risk remained largely unchanged (Additional File Text S3 includes the analysis and figures).

## 9 **Discussion**

### 10 **Main findings**

11 This nationwide study based on precise locations of residence sheds new light on the spatial variation  
12 of childhood cancer incidence in Switzerland and the extent to which this variation can be explained  
13 by environmental exposures and other spatial covariates. The spatial variation of cancer risk was small  
14 for childhood leukaemia and lymphoma and mostly explained by covariates. That of CNS tumours,  
15 particularly intracranial and intraspinal embryonal tumours, was larger and persisted after adjustment  
16 for covariates. Duration of general cancer registration in the canton was associated with higher  
17 observed cancer risk. Other covariates associated with cancer incidence included ambient air  
18 concentration of NO<sub>2</sub> for all cancers, lymphoma and leukaemia and SEP and dose rates from terrestrial  
19 gamma and cosmic background radiation for CNS tumours and all cancers.

### 20 **Comparison of our study with other spatial analyses of childhood cancer risks**

21 Compared to other studies that have investigated the spatial distribution of childhood cancers, our  
22 study stands out in that it uses precise geocoded place of residence and attempts to explain any spatial  
23 variation with commonly discussed putative environmental risk factors and completeness of  
24 registration. Our study is comparable with studies that performed parametric disease mapping, and in  
25 the lack of other studies that used LGCPs, with the two previous studies that investigated the spatial  
26 variation of childhood leukaemia risks using areal data and BYM models [8, 9, 11]. A study in France  
27 on acute leukaemia reported no evidence of spatial variation in the incidence of acute leukaemia at the

1    département level [9]. A study in Yorkshire using data aggregated on the electoral ward level reported  
2    higher childhood leukaemia risks in the less populated county of North Yorkshire [8]. We did not  
3    observe higher leukaemia risk in less populated areas. Our results are in agreement with a study in  
4    Florida that reported evidence of spatial variation of brain tumours for cases 0-19 years old [11].  
5    Other studies examining the spatial distribution of childhood cancer have focused on extra-Poisson  
6    variation and spatial clustering [32]. The general picture shows mixed results for childhood leukaemia  
7    and weak or no evidence of spatial clustering of lymphoma and CNS tumours [33-35]. In previous  
8    studies using the same data, we found no evidence of clustering of childhood cancers, leukaemia,  
9    lymphoma or CNS tumours, but weak evidence, consistent with the literature, for Hodgkin lymphoma  
10    and embryonal CNS tumours [36, 37]. We observed a cluster of intracranial and intraspinal CNS  
11    tumours in the French speaking part of Switzerland consistent with the pattern observed for CNS  
12    tumours in the present study [36].

### 13    **Comparison of our study with other studies on environmental risk factors of childhood cancer**

14    The observed spatial associations between childhood cancer risks and putative risk factors are in broad  
15    agreement with other studies that have investigated these associations disregarding the spatial context.

16    Of the included covariates in the current study, NO<sub>2</sub> showed the strongest spatial association with  
17    childhood leukaemia risks. There is increasing evidence of a link between traffic related air pollution  
18    and childhood cancers, in particular childhood leukaemia [38]. In recent meta-analyses associations  
19    with leukaemia risks were strongest for exposure to benzene and weaker for NO<sub>2</sub> [3]. Using partly  
20    overlapping data, we reported an increased risk of leukaemia among children living less than 100m  
21    from a highway [20].

22    Previous studies investigating childhood cancer risks in relation to background ionising radiation  
23    showed mixed results [21, 39-42]. While two studies reported associations between childhood  
24    leukaemia and gamma radiation [21, 39], others found no evidence of an association [40-42]. Using  
25    partly overlapping data, we previously reported evidence of associations with gamma radiation for  
26    both childhood leukaemia and CNS tumours [21]. In the current study the association was largest for

1 all cancers and CNS tumours. The evidence from other studies examining the effect of gamma  
2 radiation on the risks of CNS tumours in children was weak [39, 41].

3 Our study found evidence of an association between SEP and CNS tumours. Previous studies in  
4 Switzerland have reported weak association between socioeconomic status and childhood leukaemia  
5 incidence, but a strong effect for CNS survival [43, 44]. Our results are consistent with a large UK  
6 case-control study which reported increased risk of CNS tumours in higher social classes [45]. A  
7 recent study in Spain also reported a positive association between risk of CNS tumours and  
8 socioeconomic status [46]. In contrast, a study in North-West England [47] and a study from Norway  
9 [48] found no evidence of an association between CNS tumours and measures of socio-economic  
10 status.

### 11 **Strengths and Limitations**

12 To the best of our knowledge this is the first study attempting to model and explain the spatial  
13 distribution of childhood cancers using precise locations of residence. We used LGCPs, which  
14 represent the current state of the art for modelling such point data of disease incidence and, as we have  
15 recently shown, outperform traditional methods in identifying high risk areas [16]. These models  
16 allowed us to incorporate spatial covariates and quantify their contribution to explaining the observed  
17 spatial variation. We also tried to disentangle variation attributed to registration completeness from  
18 variation due to putative risk factors. Furthermore, in contrast to previous studies, we examined both  
19 place of birth and diagnosis. Although results were closely similar, this comparison could potentially  
20 have revealed differences in time windows of susceptibility to different risk factors. The population at  
21 risk was retrieved from national censuses and cases from a nationwide registry with high completeness  
22 [49]. We attempted to correct for potential selection bias due to regional differences in case  
23 ascertainment by including years of general cancer registration and, in post-hoc analysis, SPOG centre  
24 catchment areas.

25 Due to data availability, we could not include all potential environmental risk factors discussed in the  
26 literature, for instance pesticide exposure. Furthermore, the spatial covariates included are subject to  
27 measurement errors and do not perfectly capture the spatial variation of residential exposures. We had

1 little information about the magnitude of measurement errors, making it hard to propagate it in our  
2 modelling framework. Although we partly adjusted for differences in registration coverage, there may  
3 still be differences unaccounted for by our analyses.

#### 4 **Interpretation of findings**

5 Although the overall completeness of SCCR is larger than 95% after the mid-90s [49], we found that  
6 years of existing cancer registry can influence the apparent spatial variation of childhood cancers  
7 based on data from SCCR. This suggests that there are regional differences in registration  
8 completeness, which should be accounted for in future aetiological studies in Switzerland.

9 Our results are suggestive of an environmental aetiology for childhood CNS tumours and of  
10 aetiological differences between their histological subtypes. In post-hoc analyses, the observed spatial  
11 variation was not fully explained by differences in cancer registration in the early years of the SCCR  
12 as it persisted in the more recent periods. Neither did differences between SPOG centres, for instance  
13 in ascertainment practices, explain the spatial variation. Unmeasured environmental risk factors are  
14 thus a likely explanation. Possibly, spatial differences in the prevalence of genetic syndromes  
15 associated with these tumours might also partially explain the observed variation. In future research,  
16 there should be increased attention on putative environmental risk factors of CNS tumours, including  
17 SEP, background radiation and pesticide exposure (which was not accounted for in our analyses).

#### 18 **Conclusion**

19 This study provides evidence of spatial differences in the incidence of childhood CNS tumours in  
20 Switzerland that could be partially explained by variations in socio-economic factors and natural  
21 background radiation. The spatial variation of the risks for childhood leukaemia and lymphoma was  
22 smaller and mostly explained by measured covariates. Our study provides further support for an  
23 environmental aetiology for childhood CNS tumours, highlighting the need for future studies to  
24 distinguish between histologic subtypes.

## 1 Tables

2 **Table 1.** Number of cases and median age at diagnosis for the analysis based on the location at birth  
3 and diagnosis.

4

	Birth			Diagnosis		
	Total N	Female N	Median	Total N	Female N	Median
	(%)	(%)	Age at	(%)	(%)	Age
			diagnosis			at diagnosis
All cancers	4,198	1,875 (45)	4.8	5,947	2,654 (45)	6.4
	(100)			(100)		
Leukaemia	1,384 (33)	570 (41)	4.2	1,880 (32)	781 (42)	4.9
Lymphoma	459 (11)	161 (35)	10.2	772 (13)	279 (36)	11.5
CNS	902 (21)	421 (47)	6.0	1,290 (22)	590 (45)	7.1
tumours						

5 Abbreviations: N: number of cases, CNS: Central Nervous System

6

1 **Table 2.** Median posterior of the variance hyperparameter of the Gaussian field ( $\sigma^2$ ) for the  
 2 unadjusted and adjusted model, median posterior of variation explained ( $V(Z(s))$ ) and median

LGCPs				
	All cancers	Leukaemia	Lymphoma	CNS tumours
$\sigma^2$ unadjusted <sup>a</sup>	0.01	0	0.01	0.02
(median, 95% CI)	(0, 0.02)	(0, 0.03)	(0, 0.04)	(0.01, 0.06)
$\sigma^2$ adjusted <sup>b</sup>	0.01	0	0	0.02
(median, 95% CI)	(0, 0.03)	(0, 0.01)	(0, 0.03)	(0, 0.06)
Variation explained <sup>c</sup>	0.72	0.81	0.82	0.64
(median; 95% CI)	(0.43, 0.89)	(0.58, 0.94)	(0.60, 0.94)	(0.31, 0.84)
RR unadjusted <sup>a</sup>	0.99	1	0.99	1.01
(median; Range <sup>d</sup> )	(0.83, 1.13)	(0.96, 1.09)	(0.9, 1.13)	(0.82, 1.23)
RR adjusted <sup>b</sup>	1.02	1	1	1
(median; Range <sup>d</sup> )	(0.86, 1.08)	(0.97, 1.04)	(0.96, 1.07)	(0.87, 1.25)

3 posterior of grid specific relative risk.

4

5 Abbreviations: CI, credibility intervals; RR, grid specific relative risk compared to Switzerland as a  
 6 whole; LGCP, log-Gaussian Cox process; CNS Central and Nervous System

7 a the unadjusted model refers to the models without any covariates

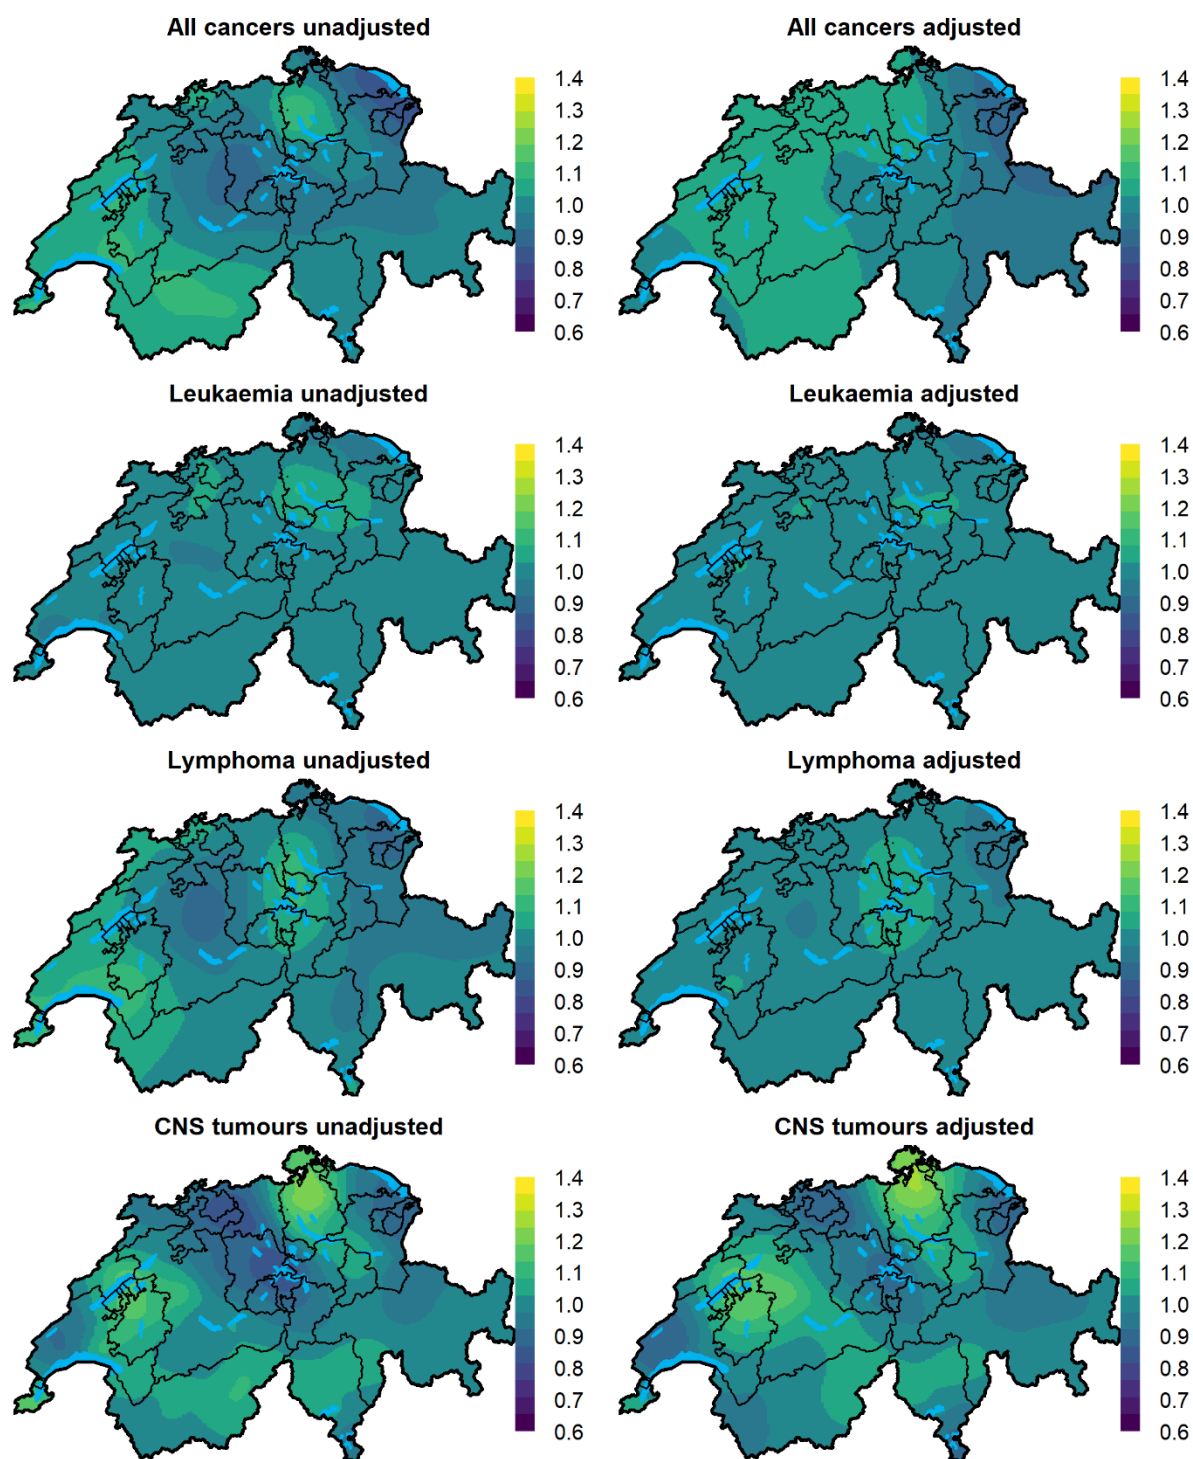

8 b adjusted for NO<sub>2</sub>, background radiation, years of general cancer registration, linguistic region and  
 9 degree of urbanicity

- 1 c variation explained by the covariates from the fully adjusted model, defined as  $R^2 = \frac{V(\mathbf{X}(s)\boldsymbol{\beta})}{V(\mathbf{X}(s)\boldsymbol{\beta})+V(Z(s))}$
- 2 where  $V(\cdot)$  denotes the variance over the  $K$  spatial units,  $\boldsymbol{\beta}$  is the vector of intercept and covariates,  $\mathbf{X}$
- 3 the design matrix and  $Z(s)$  the Gaussian field. The variation here refers to the fully adjusted model.
- 4 d Range is defined as [min, max]
- 5

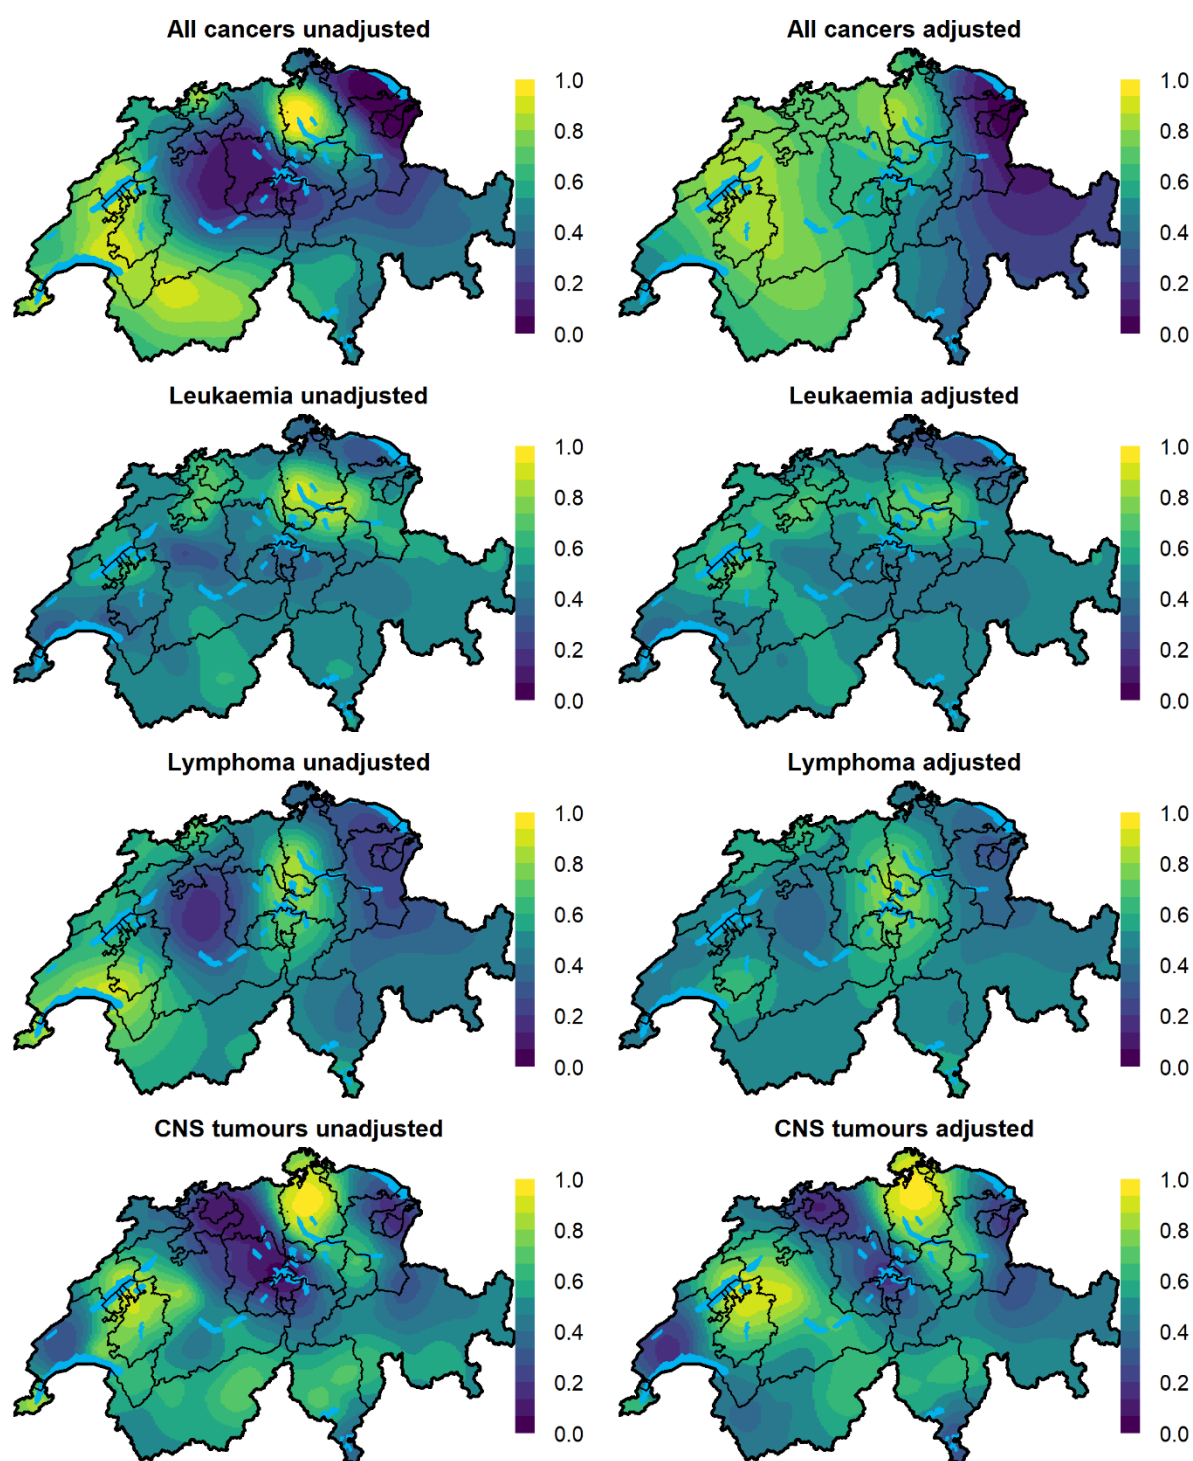

1 **Figures**

2 **Fig 1.** Maps of the median posterior of the spatial relative risk for different cancer types during 1985-  
3 2015 in Switzerland.

4  
5 The adjusted models are models adjusted for NO<sub>2</sub> total background radiation, SEP, years of cantonal  
6 registry, language region and level of urbanization.

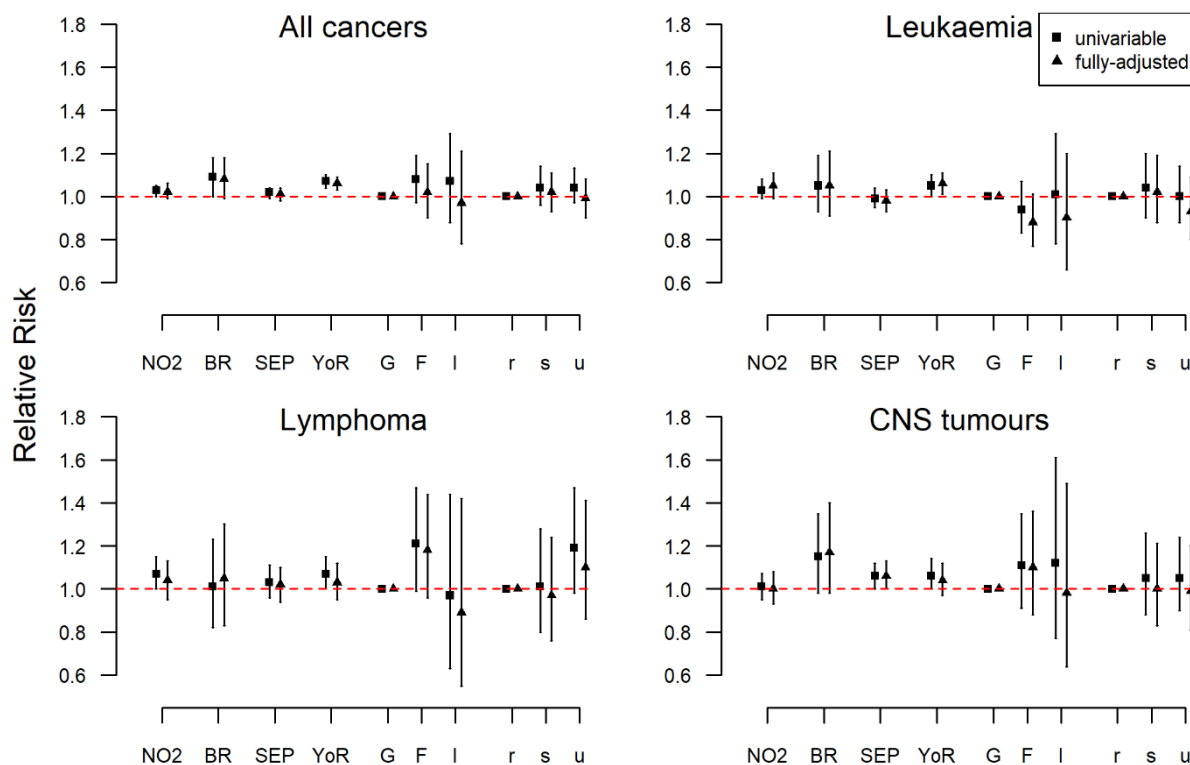

- 1 **Fig 2.** Maps of posterior probabilities that the spatial relative risk risk per grid cell is larger than 1
- 2 (exceedance probabilities) for different childhood cancers groups during 1985-2015 in Switzerland.

- 3
- 4 The adjusted models are adjusted for NO<sub>2</sub>, total background radiation, SEP, years of cantonal registry,
- 5 language region and level of urbanization.

6

1 **Fig 3.** Univariable and fully adjusted regression analysis at time of diagnosis. The fixed effects are  
 2 summarized using the posterior median of the relative risk together with 95% credibility regions.

3  
 4 Abbreviations: NO<sub>2</sub>: Nitrogen Dioxide, CNS: Central Nervous System tumours, BR: Total dose  
 5 background radiation, SEP: Socio-Economic Position, YoR: years of existing cantonal registry, G:  
 6 German speaking part, F: French speaking part, I: Italian speaking part, r: rural areas, s: semi-urban  
 7 areas, u: urban areas  
 8  
 9 NO<sub>2</sub>, total background radiation, SEP and years of cantonal registry were scaled so that the standard  
 10 deviations (SD) are 1 and considered as linear effects. Their interpretation is a multiplicative increase  
 11 (or decrease) in the number of observed cases compared to the number of the expected cases per 1 SD  
 12 increase (or decrease) in the covariate. The sd for NO<sub>2</sub> is  $77.7 \mu\text{g}/\text{m}^3 \times 10$ , for total background  
 13 radiation  $60.2 \text{ nSv}/\text{h}$ , for SEP 8.7 units and for years of cantonal registry 11.6 years.  
 14  
 15 The fully-adjusted models are models adjusted for NO<sub>2</sub>, total background radiation, SEP, years of  
 16 cantonal registry, language region and level of urbanization.

17
