## 23 **Abstract**

24 By the first week of April 2020, more than 1,500,000 positive cases of COVID-19 and  
25 more than 50,000 deaths had been officially reported worldwide. While developed  
26 countries such as the USA, Italy, England, France, Spain, and Germany struggle to mitigate  
27 the propagation of SARS-CoV-2, the COVID-19 pandemic arrived in Latin America, India,  
28 and Africa—territories in which the mounted infrastructure for diagnosis is greatly  
29 underdeveloped. An actual epidemic emergency does not provide the required timeframe  
30 for testing new diagnostic strategies; therefore, the first line of response must be based on  
31 commercially and readily available resources. Here, we demonstrate the combined use of a  
32 three-dimensional (3D)-printed incubation chamber for commercial Eppendorf PCR tubes,  
33 and a colorimetric embodiment of a loop-mediated isothermal amplification (LAMP)  
34 reaction scheme for the detection of SARS-CoV-2 nucleic acids. We used this strategy to  
35 detect and amplify SARS-CoV-2 DNA sequences using a set of in-house designed  
36 initiators that target regions encoding the N protein. We were able to detect and amplify  
37 SARS-CoV-2 nucleic acids in the range of ~625 to  $2 \times 10^5$  DNA copies by this  
38 straightforward method. The accuracy and simplicity of this diagnostics strategy may  
39 provide a cost-efficient and reliable alternative for use during the COVID-19 pandemics,  
40 particularly in underdeveloped regions where the availability of RT-qPCR instruments may  
41 be limited. Moreover, the portability, ease of use, and reproducibility of this strategy make  
42 it a reliable alternative for deployment of point-of-care SARS-CoV-2 detection efforts  
43 during the pandemics.

## 48 **Introduction**

49 By the end of the first week of April 2020, more than one and a half million positive cases  
50 of COVID-19 were officially reported across the globe[1]. Even developed countries, such

51 as the USA, England, France, and Germany, are struggling to mitigate the propagation of  
52 SARS-CoV-2 by implementing social distancing and widespread testing. Less developed  
53 regions, such as Latin America, India, and Africa, are now experiencing the arrival of  
54 COVID-19, but these—territories are woefully lacking in the finances or the mounted  
55 infrastructure for diagnosis of this pandemic infection. Rapid and massive testing of  
56 thousands of possibly infected subjects has been an important component of the strategy of  
57 the countries that are effectively mitigating the spreading of COVID-19 among their  
58 populations (i.e., China[2], South Korea [3], and Singapore [4]). By comparison,  
59 developing countries with high demographic densities, such as México [5], India [6], or  
60 Brazil [7], may not be able to implement a sufficient number of centralized laboratories for  
61 rapid large-scale testing for COVID-19.

62 Many methodologies have been proposed recently to deliver cost-effective diagnosis (i.e.,  
63 those based on immunoassays [8–11] or specific gene hybridization assisted by CRISPR-  
64 Cas systems [12–14]). While immunoassays are an accurate and efficacious tool for  
65 assessing the extent of the infection for epidemiological studies [15], their usefulness is  
66 limited to the identification of infected subjects during early phases of infection [11,16], a  
67 critical period for infectiveness. For instance, experimental evidence collected from a small  
68 number of COVID-19 patients (9 subjects) showed that 100% of them produced specific  
69 immunoglobulins G (IgGs) for SARS-CoV-2 within two weeks of infection, but only 50%  
70 of them did during the first week post infection [17].

71 Nucleic acid amplification continues to be the gold standard for the detection of viral  
72 diseases in the early stages [18–22], and very small viral loads present in symptomatic or

73 asymptomatic patients can be reliably detected using amplification based technics, such as  
74 PCR[23–25], RPA[26], and LAMP[27–29].

75 During the last two pandemic events with influenza A/H1N1/2009 and COVID-19, the  
76 Centers for Disease Control (CDC) and the World Health Organization (WHO)  
77 recommended real-time quantitative PCR (RT-qPCR) methods as the gold standard for  
78 official detection of positive cases[16,30]. However, the reliance on RT-qPCR often leads  
79 to dependence on centralized laboratory facilities for testing [16,30–33]. To resolve this  
80 drawback, isothermal amplification reaction schemes (i.e., loop-mediated isothermal  
81 amplification (LAMP) and recombinase polymerase amplification (RPA)) have been  
82 proposed as alternatives to PCR-based methods and devices for point-of-care settings  
83 [32,34,35]. The urgency of using reliable molecular-based POC methods for massive  
84 diagnostic during epidemiological emergencies has become even more evident during the  
85 current COVID-19 pandemics [30,36,37].

86 In these times of COVID-19 [38], scientists and philanthropists around the globe have  
87 worked expeditiously on the development of rapid and portable diagnostics for SARS-  
88 CoV-2. Several reports have demonstrated the use of colorimetric LAMP-based methods  
89 for diagnosis of pandemic COVID-19 [39–44]. Some of these reports (currently available  
90 as preprints) use phenol red, a well-known pH indicator, to assist in the visual  
91 discrimination between positive and negative samples [39,40].

92 In this study, we demonstrate the use of a simple embodiment of a colorimetric Loop-  
93 mediated Isothermal amplification (LAMP) protocol for the detection and amplification of  
94 synthetic samples of SARS-CoV-2, the causal viral agent of COVID-D. In this LAMP-  
95 based strategy, also assisted by the use of phenol red, sample incubation is greatly

96 facilitated by the use of a three-dimensional (3D)-printed incubator connected to a  
97 conventional water circulator, while discrimination between positive and negative samples  
98 is achieved by visual inspection. We quantitatively analyze differences in color between  
99 positive and negative samples using color decomposition and analysis in the color CIELab  
100 space[45]. Moreover, we compare the sensibility of this LAMP colorimetric method versus  
101 PCR protocols. This simple strategy is potentially adequate for the fast deployment of  
102 diagnostic efforts in the context of COVID-19 pandemics.

103

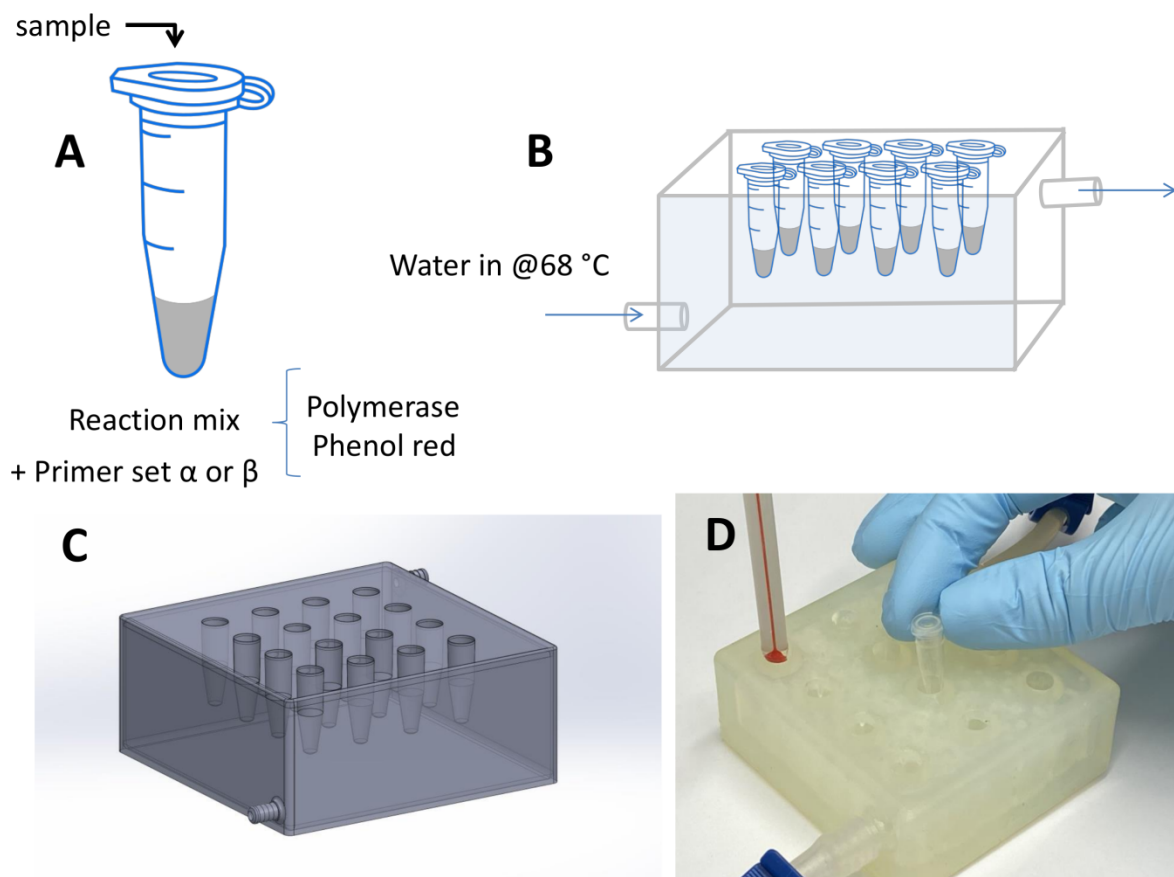

## 104 **Materials and Methods**

105 *Equipment specifications:* We ran several hundred amplification experiments using a  
106 colorimetric LAMP method in a 3D-printed incubation chamber designed in house and  
107 connected to a conventional water circulator (Figure 1). The design and all dimensional  
108 specifications of this chamber have been made available in Supplementary Information  
109 (Figure S1,S2; Supplementary File S1). In the experiments reported here, we used a  
110 chamber with dimensions of  $20 \times 5 \times 15 \text{ cm}^3$  and a weight of 0.4 kg (without water). A  
111 conventional water circulator (WVR, PA, USA), was used to circulate hot water (set point  
112 value at  $76 \text{ }^\circ\text{C}$ ) through the 3D-printed chamber for incubation of the Eppendorf PCR tubes  
113 (0.2 mL). In this first chamber prototype, twelve amplification reactions can be run in  
114 parallel. This concept design is amenable for fabrication in any STL-3D printing platform  
115 and may be scaled up to accommodate a larger number of tubes.

116 We used a blueGel electrophoresis unit, powered by 120 AC volts, to validate the LAMP  
117 amplification using gel electrophoresis. Photo-documentation was done using a  
118 smartphone camera. We also used a Synergy HT microplate reader (BioTek Instruments,

119 VT, USA) to detect the fluorescence induced by an intercalating reagent in positive  
120 samples from the PCR reactions.

121 *Validation DNA templates:* We used plasmids containing the complete N gene from 2019-  
122 nCoV, SARS, and MERS as positive controls, with a concentration of 200,000 copies/ $\mu$ L  
123 (Integrated DNA Technologies, IA, USA).

124

125 **Figure 1. Experimental setup.** (A) Commercial 200 microliter Eppendorf PCR tubes, and  
126 (B) a 3D-printed incubator were used in amplification experiments of samples containing  
127 synthetic SARS-CoV-2 nucleic acid material. (C) 3D CAD model of the LAMP reaction  
128 incubator. (D) Actual image of the Eppendorf tube incubator connected to a conventional  
129 water circulator.

130 Samples containing different concentrations of synthetic nucleic acids of SARS-CoV-2  
131 were prepared by successive dilutions from stocks (from  $2 \times 10^5$  copies to 65 copies). We  
132 used a plasmid that contained the gene GP from EBOV as a negative control. The  
133 production of this EBOV genetic material has been documented elsewhere by our group  
134 [23].

135 *Amplification mix:* We used WarmStart® Colorimetric LAMP 2× Master Mix (DNA &  
136 RNA) from New England Biolabs (MA, USA), and followed the recommended protocol:  
137 12.5 µL Readymix, 1.6 µM FIP primer, 1.6 µM BIP primer, 0.2 µM F3 primer, 0.2 µM B3  
138 primer, 0.4 µM LF primer, 0.4 µM LB primer, 1µL DNA template (~ 625 to  $2 \times 10^5$  DNA  
139 copies), 1.25 µL EvaGreen® Dye from Biotium (CA, USA), and nuclease-free water to a  
140 final volume of reaction 25 µL. This commercial mix contains phenol red as a pH indicator  
141 for revealing the shift of pH during LAMP amplification across the threshold of pH=6.8.

142

143 *Primers used:* Two different sets of LAMP primers, referred to here as  $\alpha$  and  $\beta$ , were  
144 designed in house using the LAMP primer design software Primer Explorer V5  
145 (<http://primerexplorer.jp/lampv5e/index.html>). These primers were based on the analysis of  
146 alignments of the SARS-Co2 N gene sequences using the software Geneious (New  
147 Zealand), downloaded from [https://www.ncbi.nlm.nih.gov/genbank/sars-cov-2-](https://www.ncbi.nlm.nih.gov/genbank/sars-cov-2-seqs/#nucleotide-sequences)  
148 [seqs/#nucleotide-sequences](https://www.ncbi.nlm.nih.gov/genbank/sars-cov-2-seqs/#nucleotide-sequences).

149 Each set, containing six LAMP primers, were used to target two different regions of the  
150 sequence of the SARS-Co2 N gene. In addition, for comparison purposes, we conducted  
151 PCR amplification experiments using the primer sets recommended by the CDC for the  
152 standard diagnostics of COVID-19 (i.e., N1, N2, and N3 assays) using RT-qPCR. The

153 sequences of our LAMP primers are presented in Table 1. The sequences of the PCR  
 154 primers (N1–N3) have been reported elsewhere[24,46].

155

156 *Amplification protocols:* For all LAMP experiments, we performed isothermal heating for  
 157 30 or 60 min. In our experiments, we tested three different temperatures: 50, 60, and 65 °C.

158 **Table 1. Primer sequences used in LAMP amplification experiments.** Two different sets of  
 159 primers were used, directed at the RNA sequence encoding the N sequence of the SARS-CoV-2.

Set	Description	Primers Sequence (5'>3')
<i>Primer set α</i>	2019-nCoV 1-F3	TGGACCCCAAAATCAGCG
	2019-nCoV 1-B3	GCCTTGTCCTCGAGGGAAT

	2019-nCoV 2-LB	TAACACCAATAGCAGTCCAGATGA

160

161 *Documentation of LAMP products:* We analyzed 10 μL of each LAMP reaction in a  
 162 blueGel unit, a portable electrophoresis unit sold by MiniPCR from Amplyus (MA, USA).  
 163 This is a compact electrophoresis unit (23 × 10 × 7 cm) that weighs 350 g. In these  
 164 experiments, we analyzed 10 μL of the LAMP product using 1.2 % agarose electrophoresis

165 tris-borate-EDTA buffer (TBE). We used the Quick-Load Purple 2-Log DNA Ladder  
166 (NEB, MA, USA) as a molecular weight marker. Gels were dyed with Gel-Green from  
167 Biotium (CA, USA) using a 1:10,000 dilution, and a current of 48 V was supplied by the  
168 blueGel built-in power supply (AC 100–240V, 50–60Hz).

169 As an alternative method for detection and reading of the amplification product, we  
170 evaluated the amplification products by detecting the fluorescence emitted by a DNA-  
171 intercalating agent, the EvaGreen® Dye from Biotium (CA, USA), in a Synergy HT  
172 microplate reader (BioTek Instruments, VT, USA). Briefly, 25 µL of the LAMP reaction  
173 was placed in separate wells of a 96-well plate following completion of the LAMP  
174 incubation. A 125 µL volume of nuclease-free water was added to each well for a final  
175 sample volume of 150 µL and the samples were well-mixed by pipetting. These  
176 experiments were run in triplicate. The following conditions were used in the microplate  
177 reader: excitation of 485/20, emission of 528/20, gain of 75. Fluorescence readings were  
178 done from the top at room temperature.

179

180 *Color determination by image analysis:* We also photographically documented and  
181 analyzed the progression of color changes in the positive and negative SARS-CoV-2  
182 synthetic samples during the LAMP reaction time (i.e., from 0 to 50 min). For that purpose,  
183 Eppendorf PCR tubes containing LAMP samples were photographed using a smartphone  
184 (iPhone, from Apple, USA). We used an application for IOS (Color Companion, freely  
185 available at Apple store) to determine the components of color of each LAMP sample in the  
186 CIELab color space. Color differences between the positive samples and negative controls  
187 were calculated as distances in the CIELab coordinate system according to the following  
188 formula:

189  $\text{Color Distance}_{\text{sample-negative}} = \text{SQRT} [(L_{\text{sample}} - L_{\text{negative}})^2 + (a_{\text{sample}} - a_{\text{negative}})^2 + (b_{\text{sample}} - b_{\text{negative}})^2]$

190

191 Here L, a, and b are the color components of the sample or the negative control in the

192 CIELab color space (Supplementary Figure 4).

193

## 194 **Results and Discussion**

195

### 196 **Rationale**

197 We have developed a simple diagnostic method for the detection of SARS-CoV-2, the

198 causal agent of COVID-19. The rationale underlying this strategy is centered on achieving

199 the simplest possible integration of easily available reagents, materials, and fabrication

200 techniques to facilitate fast and massive implementation during the current COVID-19

201 pandemics in low- or middle-income regions.

202 This method is based on the amplification of the genetic material of SARS-CoV-2 using a

203 loop-mediated isothermal amplification (LAMP). The amplification is conducted using a

204 commercial reaction mix in commercial and widely available 200  $\mu\text{L}$  Eppendorf PCR

205 tubes. Moreover, we have designed and fabricated a simple 3D-printed chamber (Figure 1)

206 for incubation of the Eppendorf tubes and to enable LAMP at high temperatures (50–65  $^{\circ}\text{C}$ )

207 and extended times (up to 1 h). We show that this incubation chamber, when connected to a

208 conventional water recirculator, enables the successful amplification of positive samples

209 (i.e., samples containing SARS-CoV-2 nucleic acids).

210 This incubation chamber is one of the key elements that enable rapid and widespread

211 implementation of this diagnostic method at low cost. This 3D-printed incubator can be

212 rapidly printed using standard SLA printers widely available in markets worldwide.

213 Standard 3D-printing resins can be used. The availability of the original AutoCAD files  
214 (included here as supplemental material) enables fast modification/optimization of the  
215 design for accommodation of a larger number of samples or larger or smaller tubes,  
216 adaptation to any available hoses (tubing), and possible incorporation of an on-line color  
217 reading system. Indeed, all this is consistent with the main rationale of our proposed  
218 diagnostic strategy for pandemic COVID-19: To enabling a fast and feasible response using  
219 widespread, distributed, and scalable diagnostics fabricated with widely available  
220 resources.

221 In the following section, we briefly discuss the mechanisms of amplification and visual  
222 discrimination between positive and negative samples.

223

#### 224 **Colorimetric LAMP amplification**

225 The presence of phenol red within the LAMP reaction mix allows for naked-eye  
226 discrimination between positive and negative samples. The reaction mix is coupled with the  
227 pH color transition of phenol red, a widely used pH indicator, which shifts in color from red  
228 to yellow at pH 6.8. During LAMP amplification, the pH of the reaction mix continuously  
229 evolves from neutrality to acidic values as protons are produced [27,47]. The mechanism of  
230 production of hydrogen ions ( $H^+$ ) during amplification in weakly buffered solutions has  
231 been described [47]. DNA polymerases incorporate a deoxynucleoside triphosphate into the  
232 nascent DNA chain. During this chemical event, a pyrophosphate moiety and a hydrogen  
233 ion are released as byproducts (Figure 2 A). This release of hydrogen ions is quantitative,  
234 according to the reaction scheme illustrated in Figure 2. The caudal of  $H^+$  is high, since it is  
235 quantitatively proportional to the number of newly integrated dNTPs. In fact, the

236 quantitative production of  $H^+$  is the basis of previously reported detection methods, such as  
237 the semiconductor sequencing technology operating in Ion Torrent sequencers[48].

238

239 **Figure 2. Initiators and pH indicator for SARS-Co2 detection using a colorimetric**  
240 **LAMP method.** (A) LAMP reaction scheme. (B) Chemical structure of phenol red. (C)  
241 Two different sets of LAMP primers were used for successfully targeting a gene sequence  
242 encoding the SARS-Co2 N protein. Successful targeting and amplification is clearly  
243 evident to the naked eye: positive samples shift from red to yellow.

244

245 In the initially neutral and weakly buffered reaction mixes, the production of  $H^+$  during  
246 LAMP amplification progressively and rapidly shifts the pH across the threshold of phenol  
247 red (Figure 2B).

248 Moreover, the pH shift is clearly evident to the naked eye, thereby freeing the user from  
249 reliance on spectrophotometric instruments and facilitating simple implementation during  
250 emergencies (Figure 2C). Images in Figure 2C show representative colors of the  
251 amplification reaction mixes contained in Eppendorf PCR tubes after incubation for 30  
252 min. Three different incubation temperatures were tested (50, 60, and 65 °C) and two  
253 different sets of LAMP-primers ( $\alpha$  and  $\beta$ ) were used.

254 Both sets of primers performed equivalently, at least based on visual inspection, in the three  
255 temperature conditions tested. Discrimination between positive and negative controls is  
256 possible using only the naked eye to discern the reaction products from amplifications  
257 conducted at 60 and 65 °C. No or negligible amplification was evident at 50 °C or in the  
258 control group.

259 Furthermore, we were able to successfully discriminate between positive and negative  
260 samples using LAMP reaction mix already added with primers and kept at room  
261 temperature for 48 h or at 4 °C for 72 hours (Figure S3). The stability of the reaction, the  
262 isothermal nature of the amplification process, and its independence from specialized  
263 equipment greatly simplifies the logistic of implementation of this diagnostic method  
264 outside centralized labs.

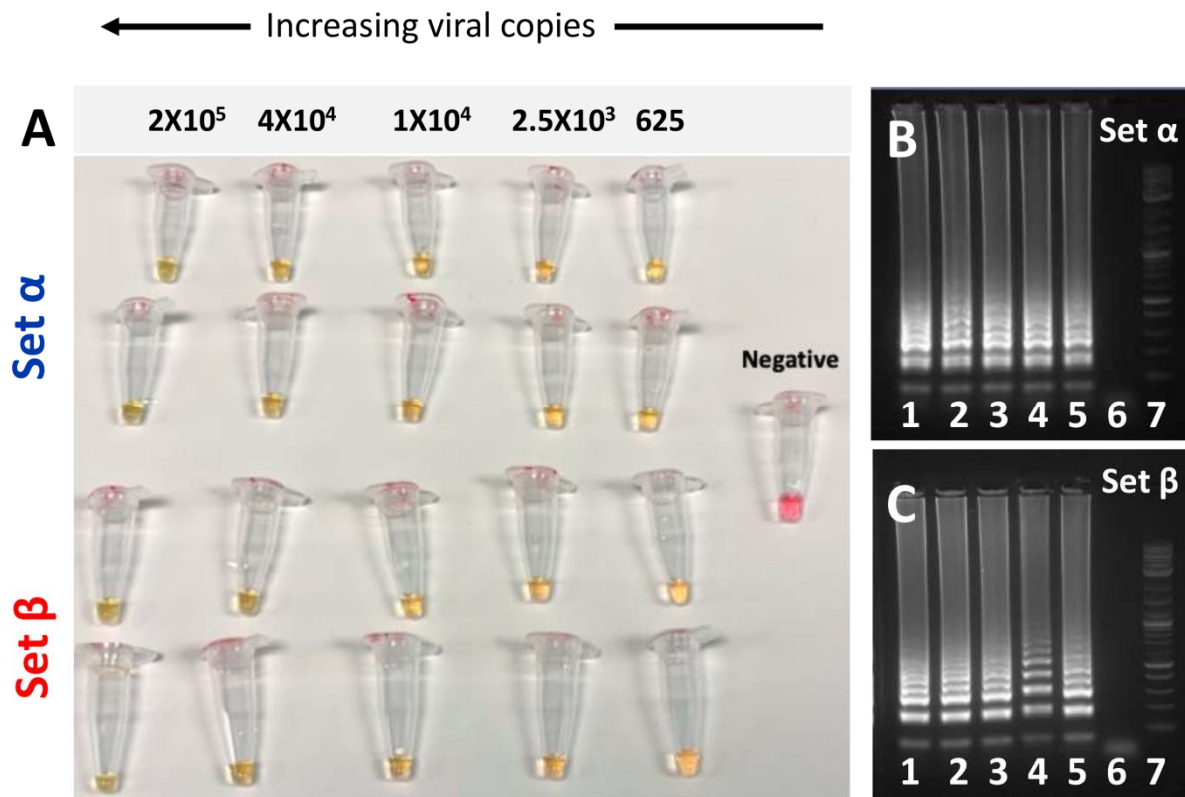

265

### 266 **Analysis of sensitivity**

267 We conducted a series of experiments to assess the sensitivity of the LAMP reactions in the  
268 3D-printed incubation chamber using the two sets of primers ( $\alpha$  and  $\beta$ ; Table 1). The  
269 amplification proceeds with sufficient quality to also allow proper visualization of the  
270 amplification products in electrophoresis gels, even at low nucleic acid concentrations. We  
271 observed that amplification proceeded successfully in a wide range of viral loads, from 625

272 to  $5 \times 10^5$  copies in experiments using synthetic SARS-CoV-2 nucleic acid material (Figure  
273 3A).

274

275

276 **Figure 3. Two different sets of LAMP-primers were used for successfully targeting of**  
277 **a gene sequence encoding the SARS-Co2 N protein.** (A) LAMP primer sets α and β both  
278 enable the amplification of synthetic samples of SARS-CoV-2 nucleic acids in a wide range  
279 of template concentrations, from 625 to  $2.0 \times 10^5$  DNA copies of SARS-CoV-2 when  
280 incubated for 50 minutes at a temperature range from 60 to 65 °C. (B,C) Agarose gel  
281 electrophoresis of DNA amplification products generated by targeting two different regions  
282 of the sequence coding for SARS-Co2 N protein. Two different primer sets were used: (B)  
283 primer set α, and (C) primer set β. The initial template amount was gradually decreased  
284 from left to right:  $2.0 \times 10^5$  DNA copies (lane 1),  $4.0 \times 10^4$  copies, (lane 2),  $1.0 \times 10^4$  copies  
285 (lane 3),  $2.5 \times 10^3$  copies (lane 4), 625 copies (lane 5), negative control (lane 6), and  
286 molecular weight ladder (lane 7).

287

288 We clearly observed amplification in samples containing as few as 625 viral copies after  
289 incubation times of 5 min at 65 °C. If we put this range into a proper clinical context, the  
290 actual viral load of COVID-19 in nasal swabs from patients has been estimated to fall  
291 within the range of  $10^5$  to  $10^6$  viral copies per mL [49]. Discrimination between positive  
292 and negative samples (controls) can be clearly established by the naked eye in all reactions  
293 incubated for 50 min, regardless of the number of viral copies present. In addition, we did  
294 not observe any non-specific amplification in negative samples (i.e., containing synthetic  
295 genetic material from EBOV) incubated for 50 min at 65 °C. Indeed, the identification and  
296 amplification of SARS-CoV-2 synthetic material is feasible in samples that contained ~62.5  
297 viral copies using this LAMP strategy (Figure S3) and incubation times of 50–60 min.

298 We corroborated the amplification by visualizing LAMP products with gel electrophoresis  
299 for the different viral loads tested. Figures 3B,C show agarose gels of the amplification  
300 products of each one of the LAMP experiments, where two different sets of primers ( $\alpha$  and  
301  $\beta$ ) were used to amplify the same range of concentrations of template (from 625 to  $2 \times 10^5$   
302 synthetic viral copies). We were able to generate a visible array of bands of amplification  
303 products, a typical signature of LAMP, for both LAMP primer sets and across the whole  
304 range of synthetic viral loads. Indeed, both primer sets rendered similar amplification  
305 profiles.

306 In summary, using the primers and methods described here, we were able to consistently  
307 detect the presence of SARS-CoV-2 synthetic nucleic acids. We have used a simple 3D-  
308 printed incubator, connected to a water circulator, to conduct LAMP. We show that, after  
309 only 30 min of incubation, samples containing a viral load in the range of  $10^4$  to  $10^5$  copies  
310 could be clearly discriminated from negative samples by visual inspection with the naked  
311 eye (Figure 2C). Samples with a lower viral load were clearly discriminated when the

312 LAMP reaction was incubated for 50 min. Incubation periods of up to 1 h at 68 °C did not  
313 induced false positives and were able to amplify as few as ~62 copies of SARS-CoV-2  
314 synthetic genetic material. These results are consistent with those of other reports in which  
315 colorimetric LAMP, assisted by phenol red, has been used to amplify SARS-COV-2  
316 genetic material [39,40].

317 We observe 0 false positive cases in experiments where synthetic samples containing  
318 EBOV genetic material were incubated at 65 °C for 1 h.

319 In the current context of the COVID-19 pandemics, the importance of communicating this  
320 result does not reside in its novelty but in its practicality. Some cost considerations follow.

321 While the market value of a traditional RT-qPCR apparatus (the current gold standard for  
322 COVID-19 diagnostics) is in the range of 10,000 to 40,000 USD, a 3D-printed incubator,  
323 such as the one described here (Figure S1,S2; Supplementary file S1), could be fabricated  
324 for under 200 USD at any 3D printer shop. This difference is significant, especially during  
325 an epidemic or pandemic crisis when rational investment of resources is critical. While the  
326 quantitative capabilities of testing using an RT-qPCR platform are undisputable, the  
327 capacity of many countries to rapidly, effectively, and massively establish diagnostic  
328 centers based on RT-qPCR is questionable. The current pandemic scenarios experienced in  
329 the USA, Italy, France, and Spain, among others, have crudely demonstrated that  
330 centralized labs are not an ideal solution during emergencies. Portable diagnostic systems  
331 may provide a vital flexibility and speed of response that RT-qPCR platforms cannot  
332 deliver.

333

334

335

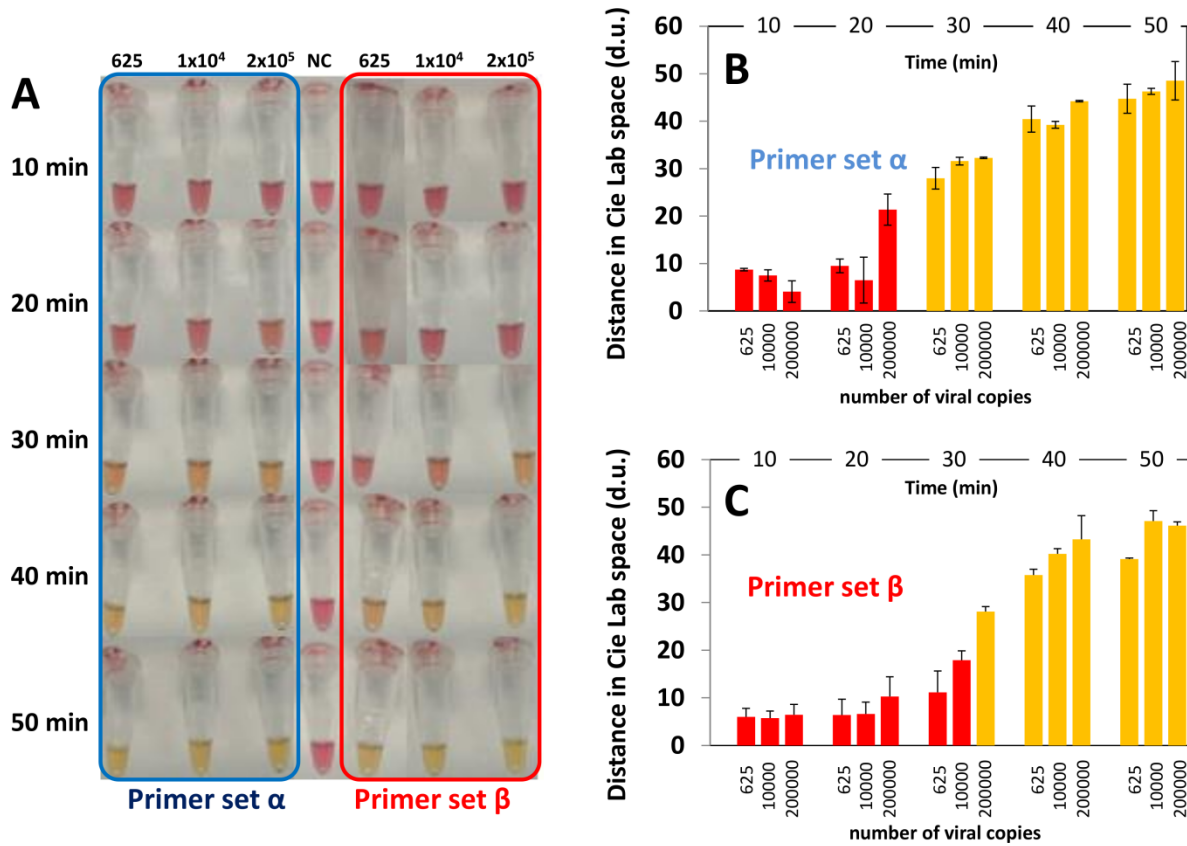

### 336 **Feasibility of real-time quantification**

337 Here, we further illustrate the deterministic and quantitative dependence between the  
338 concentration of the amplification product and the color signal produced during this  
339 colorimetric LAMP reaction. For this purpose, we simulated real-time amplification  
340 experiments by conducting a series of amplification reactions using initial amounts of 625,  
341  $1 \times 10^4$ , and  $2 \times 10^5$  copies of synthetic SARS-CoV-2 genetic material in our 3D-printed  
342 incubator.

343 We extracted samples from the incubator after 0, 10, 20, 30, 40, and 50 min of incubation at  
344 65 °C. The color of these samples was documented as images captured using a smart phone  
345 (iPhone 7) against a white background (Figure 4A). The images were analyzed using the  
346 free access application Color Companion® for the iPhone or iPad. Briefly, color images  
347 were decomposed into their CIELab space components. In the CIELab color space, each  
348 color can be represented as a point in a 3D-space, defined by the values **L**, **a**, and **b** [45]. In  
349 this coordinate system, **L** is the luminosity (which ranges from 0 to +100), **a** is the blue-  
350 yellow axis (which ranges from -50 to 50), and **b** is the green-red axis (which ranges from -  
351 50 to 50) (Figure S4).

352 The difference between two colors can be quantitatively represented as the distance  
353 between the two points that those colors represent in the CIELab coordinate system. For the  
354 colorimetric LAMP reaction mixture used in our experiments, the spectrum of possible  
355 colors evolves from red (for negative controls and negative samples) to yellow (for positive  
356 samples). Conveniently, the full range of colors for samples and controls can be represented  
357 in the red and yellow quadrant defined by **L** [0,50], **a** [0,50], and **b** [0,50]. For instance, the  
358 difference between the color of a sample (at any time of the reaction) and the color of the

359 negative control (red;  $L=53.72 \pm 0.581$ ,  $a=38.86 \pm 2.916$ , and  $b=11.86 \pm 0.961$ ) can be  
 360 calculated in the CIELab space.

361

362 **Figure 4.** Evaluation of the sensitivity of the combined use of a colorimetric LAMP method  
 363 assisted by the use of phenol red. (A) Sensitivity trials using different concentrations of the template  
 364 (positive control) and two different primers sets:  $\alpha$  (indicated in blue) and  $\beta$  (indicated in red).  
 365 Photographs of the Eppendorf PCR tubes containing positive samples and negative controls were  
 366 acquired using a smartphone. (C,D) Distance in the color CIELab space between negative controls  
 367 (red) and samples containing different concentrations of SARS-CoV-2 nucleic acid material (i.e.,  
 368 625, 10000, and 200000 synthetic copies) analyzed after different times of incubation (i.e., 10, 20,  
 369 30, 40, and 50 minutes) at 65 °C. The analysis of color distances is presented for amplifications  
 370 conducted using primer set (B)  $\alpha$  and (C)  $\beta$ .

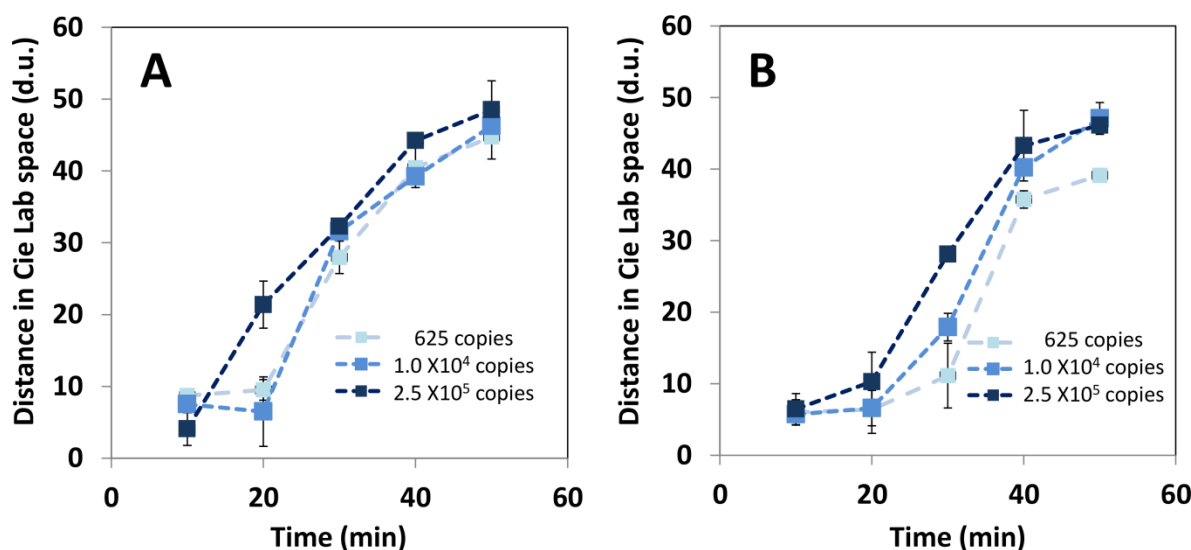

371

372 We determined the distance in the CIELab space between the color of samples taken at  
 373 different incubation times that contained SARS-CoV-2 genetic material and negative

374 controls (Figure 4B and C). We repeated this calculation for each of the LAMP primer sets  
375 that we used, namely primer set  $\alpha$  (Figure 4B) and  $\beta$  (Figure 4C).  
376 These results suggest that the color difference between the samples and negative controls is  
377 quantifiable. Therefore, color analysis may be implemented to assist the discrimination  
378 between positives and negatives. Furthermore, imaging and color analysis techniques may  
379 be implemented in this simple colorimetric LAMP diagnostic strategy to render a real-time  
380 quantitative Lamp (RT-qLAMP). Alternatively, the progression of the amplification at  
381 different times can be monitored by adding an intercalating DNA agent, (i.e., EvaGreen  
382 Dye), and measuring fluorescence on time (Figure S5).  
383 Note that the variance coefficients for the control are 1.08, 7.50, and 8.10% for L, a, and b,  
384 respectively. These small values suggest robustness and reproducibility in the location of  
385 the coordinates of the control point (reference point). Similarly, the variation in color  
386 between negative controls and positive samples incubated for 50 min was reproducible and  
387 robust (average of 46.60 +/- 4.02 d.u.; variance coefficient of 8.62%).  
388 Finally, we observed differences in the performance of the two LAMP primer sets used in  
389 the experiments reported here (Figure 4B and 5).  
390 Our results suggest that primer set  $\alpha$  enabled faster amplification in samples with fewer  
391 viral copies. Consistently, this primer set yielded positive discrimination in samples with  
392 625 viral copies in 30 min (Figure 4B). The use of primer set  $\beta$  enabled similar differences  
393 in color, measured as distances in the CIELAB 3D-space, in 40 min (Figure 4C). These  
394 findings suggest that primer set  $\alpha$  should be preferred for final-point implementations of  
395 this colorimetric LAMP method. Interestingly, primer set  $\beta$  may better serve the purpose of  
396 a real-time implementation. While primer set  $\alpha$  produced similar trajectories of evolution of  
397 color in samples that contained  $1.0 \times 10^4$  and  $2.0 \times 10^5$  viral copies (Figure 5A), primer set

398  $\beta$  was better at discriminating between amplifications produced from different initial viral  
399 loads (Figure 5B).

400

401

402 **Figure 5.** Time progression of the distance in color with respect to negative controls (red  
403 color) in the CIE Lab space for positive SARS-CoV-2 samples containing 625 (light blue,  
404  $\blacksquare$ ),  $1 \times 10^4$  (medium blue,  $\blacksquare$ ), and  $2.5 \times 10^6$  (dark blue,  $\blacksquare$ ) copies of synthetic of SARS-  
405 CoV-2 nucleic acids. Results obtained in experiments using (A) primer set  $\alpha$ , and (B)  
406 primer set  $\beta$ .

407

## 408 Conclusions

409 The challenge of point-of-care detection of viral threats is of paramount importance,  
410 particularly in underdeveloped regions and in emergency situations (i.e., epidemic  
411 outbreaks). In the context of the current COVID-19 pandemic, the availability of testing  
412 infrastructure based on RT-qPCR is recognized as a serious challenge around the world. In  
413 developing economies (i.e. Latin America, India, and most African countries), the currently  
414 available resources for massive COVID-19 testing by RT-qPCR will clearly be insufficient.

415 Even in developed countries, the time to get diagnostic RT-qPCR results from a COVID-19  
416 RT-qPCR test currently ranges from 1 to 5 days. Clearly, the available PCR labs are  
417 overburdened with samples, have too few personnel to conduct the tests, are struggling with  
418 backlogs on the instrumentation, and face complicated logistics to transport delicate and  
419 infective samples while preserving the cold chain.

420 Here, we have demonstrated that a simple embodiment of a LAMP reaction, assisted by the  
421 use of phenol red as a pH indicator and the use of a simple 3D-printed chamber connected  
422 to a water circulator, can enable the rapid and highly accurate identification of samples that  
423 contain artificial SARS-CoV-2 genetic sequences. Amplification is visually evident,  
424 without the need for any additional instrumentation, even at low viral copy numbers. In our  
425 experiments with synthetic samples, we observed 100 percent accuracy in samples  
426 containing as few as 625 copies of SARS-CoV-2 genetic material.

427 Validation of these results using real human samples from positive and negative COVID-19  
428 subjects is obviously needed to obtain a full assessment of the potential of this strategy as  
429 an alternative to RT-qPCR platforms. However, our results with synthetic samples suggest  
430 that this simple strategy may greatly enhance the capabilities for COVID-19 testing in  
431 situations where RT-qPCR is not feasible or is unavailable.
