8 **Abstract**

9 Conventional epidemiological models require estimates of important parameters including
10 incubation time and case fatality rate that may be unavailable in the early stage of an epidemic. For
11 the ongoing SARS-COV-2 epidemic, with no previous population exposure, alternative prediction
12 methods less reliant on assumptions may prove more effective in the near-term. We present three
13 methods used to provide early estimates of likely SARS-COV-2 epidemic progression. During the first
14 stage of the epidemic, growth rate charts revealed the UK, Italy and Spain as outliers, with
15 differentially increasing growth of deaths over cases. A novel data-driven time-series model was
16 then used to near-cast 7-day future cases and deaths with much greater precision. Finally, an
17 epidemio-statistical model was used to bridge from near-casting to forecasting the future course of
18 the global epidemic. By applying *multiple* approaches to global SARS-COV-2 data, coupled with
19 mixed-effects methods, countries further ahead in the epidemic provide valuable information for
20 those behind. Using current daily global data, we note convergence in near-term predictions for Italy
21 signifying an appropriate call on the future course of the global epidemic. For the UK and elsewhere,
22 prediction of peak and eventual time to resolution is now possible.

23

24

25 **Introduction**

26 Prediction of the ongoing global epidemic of SARS-COV-2 infections¹ presents a number of
 27 challenges for epidemiology, notably the apparent susceptibility of the population at large, high
 28 transmissibility of the pathogen, lack of surveillance to estimate accurate incidence, prevalence and
 29 case fatality rate (CFR)^{2,3,4,5}. Classic models of infectious disease transmission describe the processes
 30 using the law of mass action for contact transmission⁶. Refinements include mixing patterns, age
 31 stratification and spatial distribution. Whilst these models have proven extremely valuable for
 32 decision-making⁷, with validation using extended time-course datasets for multiple pathogens, they
 33 necessarily make strong parametric assumptions, from which prediction may be exponentially
 34 sensitive during the early growth phase of an epidemic. In this paper we present three
 35 complementary methods to inform on immediate, near-term (7- and 14-day) and further projection
 36 of the global SARS-COV-2 epidemic. Each method uses daily European Centre for Disease Prevention
 37 and Control (ECDC) numbers of new cases and deaths (ECDC)⁸, to inform at the individual country-
 38 level, the course of the ongoing SARS-COV-2 epidemic.

39 **Early projection using epidemic growth curves and doubling time ratios**

40 During the very earliest stage of a new epidemic, where there is effectively unrestricted transmission
 41 into a new susceptible population, with little known about the underlying disease, an exponential
 42 model of the numbers of cases and deaths is appropriate. The number of cumulative cases, $C(t)$ at
 43 time, t , is well-described using the simple exponential form, $C(t) = C_0 \exp(r(t - t_0))$, with initial
 44 number of cases C_0 at time t_0 , growth rate, r , incidence $rC(t)$ new cases per day (also exponential)
 45 and doubling time $\log(2)/r$ days. The SARS-COV-2 infection has an incubation of approximately 5
 46 days and a typical time from case presentation to death of approximately 14-21 days^{4,5}. For any case
 47 fatality rate (CFR) and duration, T , between presenting as a case and eventual death, the number of
 48 deaths at a function of time is therefore $D(t) = \text{CFR } C(t - T)$, which in the exponential phase is $D(t) =$

49 CFR $C_0 \exp(r(t - t_0 - T)) = D_0 \exp(rt)$. Hence, we predict that for any (unknown) time delay and CFR,
 50 on a log-scale cases and deaths should initially have parallel slopes, with the distance between
 51 curves at any timepoint being defined as $\log(CFR)$. Deviations from parallel log-linearity (e.g., deaths
 52 out-pacing cases), may be informative as to when healthcare systems are beginning to fail. The
 53 reported CFR will vary from country to country, hence any global assessment must adjust for
 54 differences in surveillance practice.

55 The simplest prediction method is a direct comparison of any one country with the population of all
 56 other countries rebased to the same number of cases and deaths. Figure 1a shows this prediction for
 57 the United Kingdom from all data to 21/MAR/2020. Although prediction interval is wide, when every
 58 country's cases and deaths were rebased to 64 and 4, respectively, early prediction of the UK
 59 epidemic was possible based on the same percentile growth charts familiar to any paediatrician⁹.
 60 The effects of global social distancing might be expected to move the trajectory of a country across
 61 percentiles, and this is suggested in more recent analyses (not shown).

62 A more sensitive analysis is provided using the Doubling Time Ratio (DTR), defined as the ratio of
 63 doubling times of cases compared to deaths. Figure 1b shows the correlation between exponential
 64 growth rates for cumulative cases and deaths estimated from log-linear mixed-effects models of
 65 global epidemic data (Date of analysis 21/MAR/2020), with their ratio shown (i.e., the DTR) plotted
 66 by descending DTR. The global mean exponential rate of growth of cases for the 33 countries and
 67 dependencies having reported 64 or more cases and 4 deaths, for the following 14-day period, was
 68 0.20/day (95% CI 0.16, 0.23), doubling time 3.51 days (94% CI 3.01, 4.33), between-country
 69 variability 36%. The corresponding growth rate for deaths was 0.22/day (95% CI 0.17, 0.27), doubling
 70 time 3.15 days (94% CI 2.57, 4.08), between-country variability 52%. Increased variability in deaths
 71 reflects the early stage of the epidemic. Although the estimated global DTR was 1.02 (95% CI 0.97,
 72 1.08), it is noteworthy that DTR for Italy and Spain, two EU countries particularly affected by COV-
 73 SARS-2, and the United Kingdom (DTR: 1.12, 95% CI 1.02, 1.23) were all significantly greater from

unity. A DTR of greater than unity implies that deaths are outstripping cases (for any CFR), suggesting intervention measures are necessary to prevent further unrestricted differential exponential epidemic growth. An up-to-date analysis (Date 08/APR/2020) shows movement in UK DTR (1.07, 95% CI 1.04, 1.10) relative to the Global average (1.05, 95% CI 1.03, 1.06), suggestive of the effects of social distancing.

Near-casting using time-series projection

Forward projection time-series methods have been used for many years in multiple disciplines¹⁰. Conventional time-series projections make assumptions regarding correlations in previous data to inform on future observations. Propagation of uncertainty, however, often limits precision (predictions are based on predictions not observations). The time-delay between cases and deaths inherent in the SARS-COV-2 epidemic lends itself to an alternative novel time-series methodology (Methods). Using past log-case data lagged to 7- and 14-days, and linear mixed-effects models we predict future cases based on past observations, and further predict deaths using the same model. All data is analysed in the log domain, with CFR described by a random effect to account for country-to-country variability in reporting practices. The use of dual lag times incorporates a (weekly) rate of change into the model. The minimum time delay of 7-days means that 7-day predictions are possible based on past *observations* (14-day predictions require one observation and one prediction, predictions beyond that use future predictions). This methodology opens a near-casting window on future events not available to conventional models, with the mixed-effects approach¹¹ allowing prediction in countries that are still early in their epidemic.

Figure 2 shows sample predictions for selected countries (cut-off date 08/APR/2020, rebased to 64 cases and 16 deaths, 50 countries included in the analysis dataset) of cumulative cases, deaths and incidence. The model has a residual error of 11% (Extended Data) and is useful for near-casting of the SARS-COV-2 epidemic in all countries included, with sufficient precision and sensitivity (to 7- 14-day time delays in actions) for helpful decision-making. The strength of this approach is the

99 population-method used. Information from the global epidemic informs on individual country
100 behaviour, and outlier behaviour can be identified early from individual country posterior model
101 parameters (not shown).

102 Long-term prediction using parametric epidemiological models

103 For long-term prediction, parametric epidemiological models will be necessary to control for
104 exponential time-series prediction error. However, caution is advised on model selection and
105 parameter estimation, most notably in the early epidemic phase. Conventional SEIR-type models
106 assume a law of mass action to estimate case reproductive number, R_0 , which measures the
107 transmissibility of the disease. Although intuitive, the notion of mass action, particularly in the
108 presence of significant population-level social distancing (currently in place globally), may be
109 limiting. Instead, we use the Gompertz model of epidemic growth, a limiting form of the logistic
110 model, in which log-cumulative cases is described by the differential equation $d\log C(t)/dt = r -$
111 $s\log C(t)$; r again being the unrestricted exponential growth rate, and r/s the eventual log-carrying
112 capacity. The cumulative number of log-deaths is $\log D(t) = \log CFR + \log C(t - T)$, where the $\log CFR$ is a
113 country-level case fatality rate, again modelled as a random effect to account for case reporting
114 practices. The principal deviations of this model from conventional mass-action are the brake on
115 epidemic growth (proportional to $\log C(t)$) and log-carrying capacity. Transformation to the log-
116 domain makes solution and model-fitting straightforward, controls for variability in highly non-linear
117 processes and permits log-normally distributed random effects. The use of random effects describes
118 country-to-country variability, particularly in surveillance and reporting methods, provided practices
119 remain relatively consistent within a country during the epidemic.

120 Solution of the model for cumulative $\log(\text{Cases})$ and $\log(\text{Deaths})$ for country, i , with addition of 2018
121 population as a possible covariate in the model gives:

$$122 \quad \log C_i(t) = (r_i/s)(1 - \exp(-st)) + a_{0i} \exp(-st) + a_{1i} \log N_i$$

$$\log D_i(t) = \log \text{CFR}_i + (r_i/s)(1 - \exp(-s(t - T))) + a_{0i} \exp(-s(t - T)) + a_{1i} \log N_i,$$

where (r_i/s) is the log-final epidemic size (r_i being a random effect), a_{0i} the intercept (epidemic initiation, also a random effect), $\log N_i$ the reported 2018 World Bank population, and $\log \text{CFR}_i$ the individual country log-case fatality rate. The three random effects presume log-normal global distributions for epidemic initiation, eventual epidemic size and CFR.

Figure 3 shows results of the individual country predictions selected countries from analysis of global ECDC data (08/APR/2020 rebased to 128 cases and 32 deaths, 50 countries included in the analysis dataset). Overlaid is the time-series near-casting prediction for comparison and quality control. Where the epidemic shows significant curvature, estimation of peak incidence of death and overall epidemic size is possible. At the global level, population parameters are all well-estimated (Extended Data), without significant correlation for projection. The estimated global unrestricted epidemic growth rate is 0.69/day (95% CI 0.65, 0.73) – in a Gompertzian model, observed exponential growth is always less than r , between-country variability 73%, with CFR 6.3% (95% CI 4.9, 7.7), between-country variability 69%. Model residual for cases and deaths (modelled simultaneously with equal log-residual) is only 12%. Caution is necessary, however, regarding model interpretation – particularly eventual epidemic size, because model *selection* (as opposed to parameter estimation) may be invalid if unqualified by the near-casting model.

Discussion

In the ongoing SARS-COV-2 epidemic, multiple methods are available for projection of numbers of cases and deaths. Without a means of projection, evaluation of the effectiveness (or otherwise) of intervention methods will prove challenging. Traditional epidemiology models based on contact and transmission patterns are important for planning intervention policies (e.g., mass vaccination and treatment), but they may struggle with calibration in a new setting when key parameters for their evaluation are poorly known. SARS-COV-2 presents such an example; an emergent global epidemic where previous immunity is absent. Robust intervention decisions will, however, be insensitive to

parameter assumptions, and the predictions of Ferguson et al⁷, that there are no good outcomes without population intervention are therefore robust. In this analysis, we show that even in the absence of (key) epidemiological parameters (accurately known incubation time, underlying case fatality rate and transmissibility), by taking a global approach to the epidemic, it is possible to provide an early accurate assessment. We have shown that a simple “growth chart”, calculated from rebased case and death data from all countries other than the one of interest, was able to make an early prediction of the course of the UK SARS-COV-2 epidemic. This analysis, coupled with estimation of global log-linear growth rates for cases and deaths showed that the UK was likely to be an outlier, and that intervention was likely necessary. The Doubling Time Ratio for the UK showed that deaths were doubling 12% faster than cases, and faster than the global average, during the initial exponential phase ($P < 0.05$ compared with a global estimate of equality), possibly implicating strain on healthcare services from an early stage of the epidemic. Similar findings were noted in both Italy and Spain.

Such a simple model is useful for immediate prediction but makes a strong assumption regarding future time course and is obviously unsuited to the first outbreak (in this case in Wuhan). It only assumes that progression (on a log scale) will follow other countries when rebased to the same point in the epidemic. Prediction intervals are necessarily very wide but still useful for the immediate (7- to 14-day time-frame) near-casting. Refinements such as scaling for population size (which was not available in the original ECDC dataset) may be unnecessary when an early epidemic is confined to the regional scale with population size of order 10^6 (i.e., Wuhan Province, Northern Italy, London).

Once in the exponential growth phase, data-driven prediction is necessary. The characteristics of the epidemic (pseudo-exponential growth and an incubation from case presentation to eventual death) lend themselves to novel time-series analysis. We find that rebasing global data to a common number of cases, using 7- and 14-day lagged log-cumulative cases, and application of linear mixed-effects models (accounting for country-to-country variability), can be used to near-cast epidemic

direction. The advantage over traditional time-series approaches is that the first 7-days of predictions are founded on past observations (not future predictions), thereby reducing (exponential) error. Case fatality rate differences were well-described at the country level by a log-linear random effect.

For eventual long-term forecasting, a parametric epidemiological model is necessary. Without such a model, a call on the location and size of the peak, and eventual size and duration of the epidemic, is not possible. These parametric models suffer from uncertainties and parameter correlations that make initial estimation and future very challenging from single country data. However, we find that using global, rather than individual country, data, a non-linear mixed-effects Gompertz epidemiological statistical model can describe the epidemic well with excellent parameter estimation and low residual. Providing a prediction of the time course for any single country from the model, however, requires some form of quality control. That quality control is provided by the near-casting model. Once near-term prediction intervals for the two modelling approaches coalesce, it is possible to move from near-casting to forecasting with confidence. Based on our most up-to-date analysis, this coalescence has happened in Italy, and it is now possible to provide more confident forward projections for that country and others.

The power of the epidemiological-statistical global mixed-effects analysis is that, like the two previous approaches, countries further advanced in their epidemic inform on those following behind. We find concordance between the two approaches in Italy, with support for an eventual epidemic size of approximately 31.8k (95% CI 28.8k, 35.2k) deaths, with resolution by the beginning of July 2020. Using the model, we also find support for a peak in the UK epidemic somewhere from 7/APR/2020 to 21/APR/2020, approximately 22.6k (95% CI 12.3, 26.5k) deaths, and resolution also by July 2020. It is still too early to call the eventual global epidemic size, although values are predicted for every country in the analysis dataset. All predictions are founded on a continuation of the current global social distancing intervention program, which supports the use of a Gompertz epidemiological

model. A relaxation of restrictions would release the brake on contacts, increase transmission, invalidate future model assumptions, and most-likely lead to an extension of the epidemic duration. Such predictions are out of scope for this analysis.

Methods

Daily global data on new cases and deaths was downloaded from EDCD. Cumulative cases and deaths were log-transformed for analysis. Data was selected based on number of rebased cases, and time rebased from this point. Growth rate charts were calculated from geometric mean and percentiles assuming log-normal distribution, with doubling time estimated by log-linear regression. Doubling Time Ratio was estimated by separate log-linear random effects models, growth rates merged, and 95% confidence intervals calculated. For time-series projection, log-cumulative cases were lagged by 7- and 14-days prior to fitting a log-linear mixed-effects model with random intercept and slopes. Log-cumulative deaths was fitted to predicted number of cases, also with random intercept and slope. The epidemio-statistical Gompertz model was fitted to the same analysis dataset. Predictions (mean and 95% CI) were back-transformed, differenced (for incidence calculation) and overlaid with observation. Model goodness of fit was assessed visually and by Bayes Information Criteria. All analyses were conducted in SAS 9.4 proc mixed and proc nlmixed, automated by scripting and available from the author. At the time of publication, daily updated global projections are ongoing.

Figure 1

a) Growth curve for 2020 SARS-COV-2 global epidemic with UK data (not included in curve estimation) overlaid rebased to 64 cases and 4 deaths. Geometric mean and 95% CI, median, interquartile and interdecile ranges indicated. Data to 21/MAR/2020. b) Global exponential growth rates for cumulative cases and deaths with UK indicated (21/MAR/2020, data rebased to 64 cases and 4 deaths and fitted with a log-linear mixed effects model). c) Growth Rate Ratios for all countries, values greater than unity indicate that the rate of growth of deaths is greater than cases and may signify strains on healthcare (Data to 21/MAR/2020).

290 **Figure 2**

291 Near-term prediction of the ongoing UK SARS-COV-2 epidemic (mean and 95% prediction interval)
292 for the dual-lagged linear mixed effects model. Model shows cumulative cases and deaths and daily
293 case and mortality incidence. Near-casting (7-day) projection indicated. Data to 08/APR/2020.

296 **Figure 3**

297 Posterior predicted course of the SARS-COV-2 epidemic for selected countries with near-term dual
 298 lagged model predictions overlaid. Concordance in short-term predictions improves confidence in
 299 the long-term projection Lack of concordance between prediction methods means that it is too early
 300 to call the final size and shape of the UK epidemic.

United_Kingdom

Prediction based on global Epidemiological model rebased to 128 cases and 64 deaths onw ards
Geometric mean and 95% prediction interval show n. Data from ECDC <https://www.ecdc.europa.eu> dated 2020-04-08

Italy

Prediction based on global Epidemiological model rebased to 128 cases and 64 deaths onw ards
Geometric mean and 95% prediction interval show n. Data from ECDC <https://www.ecdc.europa.eu> dated 2020-04-08

Spain

Prediction based on global Epidemiological model rebased to 128 cases and 64 deaths onw ards
Geometric mean and 95% prediction interval show n. Data from ECDC <https://www.ecdc.europa.eu> dated 2020-04-08
