22 **Abstract**

23 The causes of multiple sclerosis (MS) remain unknown. Smoking has been associated with
24 MS in observational studies and is often thought of as an environmental risk factor. We used
25 two-sample Mendelian Randomization (MR) to examine whether this association is causal
26 using genetic variants identified in genome-wide association studies (GWAS) as associated
27 with smoking. We assessed both smoking initiation and lifetime smoking behaviour (which
28 captures smoking duration, heaviness and cessation). There was very limited evidence for a
29 meaningful effect of smoking on MS susceptibility was measured using summary statistics
30 from the International Multiple Sclerosis Genetics Consortium (IMSGC) meta-analysis,
31 including 14,802 cases and 26,703 controls. There was no clear evidence for an effect of
32 smoking on the risk of developing MS (smoking initiation: odds ratio [OR] 1.03, 95%
33 confidence interval [CI] 0.92-1.61; lifetime smoking: OR 1.10, 95% CI 0.87-1.40). These
34 findings suggest that smoking does not have a detrimental consequence on MS susceptibility.
35 Further work is needed to determine the causal effect of smoking on MS progression.

36

37 **Background**

38 Smoking is an avoidable environmental cause to many life-threatening diseases such as lung
39 cancer, heart and respiratory disorders (1,2). There is emerging evidence linking cigarette
40 smoke to conditions negatively affecting the central nervous system (CNS), like multiple
41 sclerosis (MS) (3,4). MS is a chronic neurological disorder causing autoimmune breakdown
42 of the myelin sheath surrounding axons in the CNS (5). The disease is characterised by
43 periods of disease activity followed by remission and/or progressive neurological decline,
44 resulting in increasing disability (6). Like most autoimmune conditions, there is no known
45 specific cause; however, we know there is an interaction between genetic and environmental

46 factors in susceptible individuals, that go on to develop the disorder (7). Unfortunately, there
47 is no cure for MS(8), and people diagnosed often live with extreme disability (9). There are
48 emerging treatments aimed at modifying the disease course (10), but they are not universally
49 effective particularly with regards to the progressive form of the disease. Therefore, it is
50 important to continue targeting prevention by means of establishing causal links.

51 Evidence from observational epidemiological studies suggests that smoking increases MS
52 risk (11). It is hypothesised from experimental studies that exposure to chemicals in cigarette
53 smoke alter the immune cell balance in the lung (12,13) which in turn can lead to generalised
54 pro-inflammatory effects that trigger autoimmunity (14,15), in genetically susceptible
55 individuals (16,17). In addition, cigarette chemicals contribute mechanistically to MS
56 pathobiology. Specifically, nicotine increases the permeability of the blood-brain barrier (18);
57 cyanide contributes to demyelination (19); and nitric oxide causes degeneration of axons
58 (20). There is evidence for an association between smoking and worsening symptoms,
59 number of relapses, lesion load on MRI, brain atrophy rate (15) and the rapidity of disability
60 progression in MS patients (4,21,22).

61 However, it is hard to make causal inferences from observational studies which can be biased
62 by issues of reverse causation and residual confounding. One method which can be used to
63 reduce these sources of bias is Mendelian Randomization (MR) (23). MR can be
64 implemented through instrumental variable analysis that uses genetic variants to proxy the
65 exposure (e.g, smoking) and estimate a causal effect of that exposure on the outcome (e.g,
66 MS). The MR method makes three important assumptions: 1) the genetic variants must
67 robustly predict the exposure, 2) the genetic variants must not be associated with any
68 confounders and 3) the genetic variants must only affect the outcome through the exposure
69 (24). To satisfy the first assumption we selected the most recently available genetic
70 instruments from previously conducted genome-wide association studies (GWAS) associated

71 with smoking behaviour (smoking initiation (25) and lifetime smoking (26)) that can be
72 implemented in a two-sample MR context (Fig 1). The latter two assumptions can be violated
73 by horizontal pleiotropy which occurs when the genetic variants affect the outcome other
74 than through the exposure. We test for this possibility using multiple sensitivity analyses.

75 **Fig 1. Directed acyclic graph of the Mendelian randomization framework investigating**
76 **the causal relationship between smoking and multiple sclerosis.** Instrumental variable
77 assumptions: IV1: the instruments must be associated with the exposure; IV2: the instruments
78 must influence MS only through smoking; IV3: the instruments must not associate with
79 measured or unmeasured confounders in the smoking to MS relationship.

80 **Results**

81 **Smoking initiation**

82 The inverse-variance weighted MR estimate (OR 1.03, 95% confidence interval (CI) 0.92 -
83 1.16) revealed no strong evidence for a causal effect of the genetic risk of smoking initiation
84 on incidence of MS (Fig 3). This was consistent across all MR methods employed, providing
85 further support for the result as each MR method has different assumptions and therefore tests
86 for different violations of those assumptions. Indeed, the weighted median and weighted
87 mode only allow SNPs in the largest homogeneous cluster to contribute to the overall
88 estimate and provide estimates with confidence intervals overlapping the null (Fig 3 and
89 Supplementary Fig 1). The 371 SNPs used as genetic proxies for smoking initiation (Fig 2a
90 and Supplementary Table 1) had an F statistic of 44.90 indicating a strong instrument and that
91 weak instrument bias was unlikely to be influencing the effect estimates. There was evidence
92 of heterogeneity with a large Cochran's Q statistic of 559.48, $p=6.65 \times 10^{-6}$ and the MR-
93 PRESSO global test value of 562.12, $p<0.000125$. However, this not indicative of directional
94 horizontal pleiotropy given the consistent MR Egger estimate (OR 1.13, 95% CI 0.67 to

95 1.91), small intercept (0.0017, $p=0.73$) and symmetrical funnel plot (Supplementary Fig 2).
96 Similarly, MR-RAPS is robust to systematic and idiosyncratic pleiotropy, accounting for
97 weak instruments, pleiotropy and extreme outliers, and gave a similar causal estimate (OR
98 1.05, 95% CI 0.93 to 1.17). Furthermore, MR-PRESSO removes individual SNPs that
99 contribute to heterogeneity disproportionately more than expected in order to reduce
100 heterogeneity. The MR-PRESSO outlier corrected causal estimate was 1.040 (95% CI 1.040
101 to 1.041). Therefore, the second IV assumption (known as the exclusion restriction
102 assumption) of MR has not been violated and directional pleiotropy is unlikely to be biasing
103 the estimates, even though the outlier removal automatically leads to over precise estimates.
104 Leave-one-out and single SNP analyses (Supplementary Fig 3 and 4) were conducted as
105 sensitivity tests sequentially omitting one SNP at a time and performing MR using a single
106 SNP respectively to assess the sensitivity of the results to individual variants. These indicated
107 that there is not a single SNP driving the association whose effect is being masked in the
108 overall analysis. The exclusion of exposure variants located within the MHC did not alter the
109 null association between smoking initiation and incidence of MS (Supplementary Table 2).

110 **Fig 2. Flowchart for selection of genetic variants associated with smoking initiation (A)**
111 **and lifetime smoking (B).** Abbreviations: GSCAN: GWAS & Sequencing Consortium of
112 Alcohol and Nicotine use; GWAS: Genome-Wide Association Study; LD: Linkage
113 Disequilibrium; MS: multiple sclerosis; IMSGC: International Multiple Sclerosis Genetics
114 Consortium; MR: Mendelian Randomization; SNP: Single-Nucleotide Polymorphism.

115 **Fig 3: Two-sample Mendelian Randomization estimates of the association between**
116 **smoking initiation and incidence of multiple sclerosis.** Odds ratios are expressed per unit
117 increase in log odds of ever smoking regularly (smoking initiation). MR: Mendelian
118 Randomization; OR=Odds Ratio; CI=Confidence Intervals; p.val: p value.

119 **Lifetime smoking**

120 There was no clear evidence for a causal effect of the genetic risk of lifetime smoking on
121 incidence of MS (Fig 4). The 125 SNPs used as genetic proxies for lifetime smoking (Fig 2b
122 and Supplementary Table 3) had an F statistic of 44.05 indicating a strong instrument that is
123 unlikely to cause the effect estimates to be affected by weak instrument bias. The inverse-
124 variance weighted MR analysis estimate (OR 1.10, 95% CI 0.87 to 1.40) revealed no strong
125 evidence for a causal effect of the genetic risk of lifetime smoking on incidence of MS and
126 was consistent across all MR methods employed (Fig 4 and Supplementary Fig 5). There was
127 evidence of heterogeneity among the individual SNP effect estimates for lifetime smoking
128 with a large Cochran Q statistic (156.18, $p=0.02$) and MR-PRESSO global test estimate of
129 158.4895, $p=0.03$. However, this was not supported by the symmetrical funnel plot
130 (Supplementary Fig 6) nor by any outliers detected in the MR-PRESSO test. Furthermore, the
131 small MR Egger intercept (-0.003 , $p=0.69$) and consistent MR Egger estimate (OR 1.34, 95%
132 CI 0.49 to 3.65) suggests that the magnitude of potential bias from directional pleiotropy is
133 low. Furthermore, there was no single SNP driving the association whose effect is being
134 masked in the overall estimate as demonstrated by the leave-one-out and single SNP
135 sensitivity analyses (Supplementary Fig 7 and 8). MR excluding the lifetime smoking
136 associated variant located within the MHC region yielded consistent results overlapping the
137 null (Supplementary Table 4).

138 **Figure 4: Two-sample Mendelian Randomization estimates of the association between**
139 **lifetime smoking and incidence of multiple sclerosis.** Odds ratios are expressed per 1
140 standard deviation increase of the lifetime smoking index. MR: Mendelian Randomization;
141 OR=Odds Ratio; CI=Confidence Intervals; p.val: p value.

142

143 A bidirectional analysis shows that there was no clear evidence that a genetic predisposition
144 to MS is associated with either smoking initiation or lifetime smoking (Supplementary Table
145 5 and 7). MR of MS associated variants located within the MHC region yielded consistent
146 results overlapping the null (Supplementary Table 6 and 8).

147

148 **Discussion**

149 This study uses the MR method to estimate the causal effect of smoking on risk for MS.

150 Using a two-sample MR design in 14,802 MS cases and 26,703 controls, we found little

151 evidence that both genetically predicted smoking initiation and lifetime smoking are

152 associated with MS risk. These findings suggest that smoking is not a clear environmental

153 risk factor for MS susceptibility and are in line with a recent independent study (27).

154 Although a small effect cannot be entirely excluded, the relatively narrow confidence

155 intervals, particularly for smoking initiation, make a clinically relevant effect less likely.

156 This contradicts previously reported observational studies that show an association with MS

157 risk among smokers, compared to non-smokers, of a meta-analysed effect estimate odds ratio

158 of 1.5 (4,11). The studies included limitations such as self-report MS diagnosis (28),

159 participation rate less than 80% (29–31) and loss to follow up (32). Additionally,

160 observational studies may have heterogenous results due to how smoking status was defined

161 (11). The strength of association and causality between smoking and MS risk has been

162 suggested due to a dose-dependent relationship in duration and intensity of smoking (4,33) as

163 well as from the interaction between compounds present in cigarettes and specific genetic

164 HLA variants, which include the presence of HLA-DRB1*15, the absence of HLA-A*0201

165 (34) and specific N-acetyltransferase 1 (NAT1) polymorphisms (35). These genetic variants

166 facilitated epitope cross-reactivity and activation of T cells and smoking may strongly

167 influence the risk of MS observed with these HLA genotypes. However, other studies have
168 failed to replicate this interaction (36,37). In order to test this interaction in an MR casual
169 inference context, a factorial MR design in MS patients with and without those alleles would
170 be required. This was not possible in the present study due to the use of GWAS summary
171 statistics. Observational estimates may have also been biased by residual or unmeasured
172 confounding from factors influencing both smoking status and MS. For example, co-
173 morbidities and socioeconomic status may influence the likelihood of being a smoker and
174 having MS (15,38).

175 Reverse causation could also partly explain the discrepancy between our MR results and
176 observational studies especially as MS onset may occur long before the first clinical
177 symptoms (39). For instance, this prodromal phase is characterized in part by a higher risk of
178 depression and anxiety up to 10 years prior to MS diagnosis (40), and these in turn are
179 associated with a higher rate of smoking. This study sought to reduce bias from confounding
180 and reverse causation by using a MR design given genetic variants are much less associated
181 with confounders than directly measured environmental exposures (41) (here smoking) and
182 genetic variants are fixed over our lifetime ensuring directionality of effect. This is a major
183 strength of this study in establishing causality in the relationship between smoking and MS
184 risk. Additionally, MR reverse direction MR was performed and shows that reverse causation
185 is unlikely to be playing a role. A further strength of this study is the use of robust genetic
186 instruments which are strong predictors of smoking behaviour. Finally, we used multiple MR
187 methods and sensitivity analyses to test for bias from directional horizontal pleiotropy. Our
188 estimates were consistent across these multiple methods, strengthening our conclusions.

189 The current study cannot inform us about the effects of smoking on MS symptom severity,
190 disability or progression of disease. Indeed, smoking shows an association with disease
191 progression, disease activity (new lesions on magnetic resonance imaging (MRI); clinical

192 relapse rates) and brain atrophy (15). Observational studies have shown an association
193 between smoking and progression from relapsing remitting MS to secondary progressive MS
194 with a dose-response relationship (42–46) as well as a faster rate increasing Expanded
195 Disability Status Scale (EDSS) (22). However, more research in this area is needed to for a
196 definitive conclusion of an effect and specific mechanisms of action. As new methods are
197 being developed to assess disease progression using MR (47), when a GWAS of MS
198 progression becomes available, future studies should explore the association between
199 smoking and the different measures of MS progression in a MR framework.

200 The instrument predicting smoking initiation and lifetime smoking were broadly distinct
201 (only 9 SNPs overlapping). The measure of lifetime smoking exposure takes into account
202 smoking status and, among ever smokers, duration, heaviness and cessation. Although our
203 lifetime smoking instrument captured smoking heaviness in part, however we were unable to
204 explore whether there was a dose-response relationship between the number of cigarettes
205 smoked and the likelihood of developing MS given we were unable to stratify the MS GWAS
206 by smoking status. Most, but not all (30,48,49), evidence to date seems to suggest that there
207 is a positive correlation between the amount smoked and the severity of illness
208 (4,31,37,43,50–53). It might be that rather than a causal relationship between smoking and
209 MS risk, that smoking instead accelerates the disease process in those that would have
210 already developed MS.

211 Limitations of this study are, firstly, that although we assessed pleiotropy using MR methods
212 that account for pleiotropic effects, pleiotropy can only be addressed indirectly, and some
213 SNPs may relate to MS risk through pathways other than smoking. We did not find evidence
214 for bias for horizontal pleiotropy using the MR Egger intercept test nor the funnel plots which
215 did not reveal evidence of directional, or unbalanced, pleiotropy. Secondly, this study was a

216 two-sample MR using MS meta-analysis summary statistics and therefore this does not allow
217 for gene-environment interaction or sex stratified analysis.

218 In conclusion, we find no clear evidence for a causal effect of smoking on the risk of
219 developing MS. Previous observational results may have been due to confounding factors,
220 which we have avoided through our analysis. Future research should focus on the effect of
221 smoking on the disease course of MS and its effect on progression.

222

223 **Methods**

224 **Genetic instruments for smoking**

225 *Smoking initiation.* We used the most recent GWAS of smoking initiation from the GWAS &
226 Sequencing Consortium of Alcohol and Nicotine use (GSCAN) consortium which identified
227 378 conditionally independent genome-wide significant SNPs in a sample of 1,232,091
228 individuals of European ancestry. These genetic variants explain 2% of the variance in
229 smoking initiation(25).

230 *Lifetime smoking.* In order to incorporate measures of smoking heaviness without having to
231 stratify on smoking status (which is not possible in the two-sample MR context without a
232 stratified GWAS of MS), we used the GWAS of lifetime smoking conducted in 462,690
233 individuals of European ancestry from the UK Biobank (26). Lifetime smoking is a
234 combination of smoking initiation, duration, heaviness and cessation described in detail
235 elsewhere (26). This GWAS identified 126 independent genome-wide significant SNPs that
236 explain 0.36% of the variance(26).

237 **Genetic variants associated with multiple sclerosis**

238 Effect estimates and standard errors for smoking associated SNPs on MS susceptibility were
239 obtained from the summary statistics of the discovery cohorts of the latest International
240 Multiple Sclerosis Genetics Consortium (IMSGC) meta-analysis, including 14,802 cases and
241 26,703 controls (54). All details relating to demographic characteristics, MS case
242 ascertainment and eligibility criteria for the meta-analysis can be found in the original
243 publication (54). For SNPs not available in the IMSGC dataset, we identified proxy SNPs in
244 high linkage disequilibrium ($r^2 > 0.8$) using an online tool LDlink
245 [<https://ldlink.nci.nih.gov/?tab=ldproxy>], giving a total of 371 SNPs for smoking initiation
246 instrument and 125 SNPs for lifetime smoking (Figure 2 and Supplementary Table 1 and 2).

247

248 **Mendelian Randomization analyses**

249 A two sample MR was undertaken to obtain effect estimates of genetically predicted smoking
250 on MS susceptibility, using both initiation and lifetime proxy measures. MR and sensitivity
251 analyses were performed in R (version 3.5.1) using the TwoSampleMR R package
252 (<https://mrcieu.github.io/TwoSampleMR/>) (55) with effect estimates compared across five
253 different methods: inverse variance weighted (IVW); MR Egger (56); weighted median (57);
254 weighted mode (58); robust adjusted profile score (RAPS) (59); pleiotropy residual sum and
255 outlier (PRESSO) (60). Given the different assumptions that each of these methods make
256 about the nature of pleiotropy, consistency in the point estimate across the methods
257 strengthens causal evidence (61). The IWV method is the main analysis and the other
258 methods provide sensitivity analyses. Instrumental variable analysis of MR is based on a ratio
259 of the regressions of the genetic instrument-outcome association (weighted smoking
260 associated SNPs with MS from IMSGC) on the genetic instrument-exposure association
261 (smoking associated SNPs with smoking initiation or lifetime smoking in the independent
262 smoking GWASs). For smoking initiation, the odds ratios are expressed per unit increase in

263 log odds of ever smoking regularly (smoking initiation); for lifetime smoking, the odds ratios
264 are expressed per 1 standard deviation increase of the lifetime smoking index.

265 Additional sensitivity analyses were performed in order to formally test for potential
266 violations of MR assumptions. The mean F statistic was calculated as an indicator of
267 instrument strength (a value of >10 indicates a strong instrument) and the Cochran's Q
268 statistic was assessed as a measure of heterogeneity for the IVW method to estimate whether
269 the individual SNP effects of smoking on MS were inconsistent. The MR Egger intercept was
270 assessed to detect directional pleiotropy where the genetic instruments would be influencing
271 MS through another pathway other than smoking. To identify potentially influential SNPs,
272 which could be driven for example by horizontal pleiotropy, we used leave-one-out and
273 single-SNP MR analyses. Additionally, due to the strong genetic signal for MS within the
274 MHC region and high potential for pleiotropy, MR analysis excluding exposure variants
275 located within the extended major histocompatibility (MHC) region was performed (defined
276 as base positions 24,000,000 to 35,000,000 on chromosome 6 [GRCh37]).
