85 Abstract

86

87

income countries (LMICs) as a clean energy alternative to biomass burning cookstoves.
Objective: We sought to characterize kitchen area concentrations and personal exposures to

Background: Liquefied petroleum gas (LPG) stoves have been promoted in low- and middle-

nitrogen dioxide (NO₂) within a randomized controlled trial in the Peruvian Andes. The
intervention included the provision of an LPG stove and continuous fuel distribution with
behavioral messaging to maximize compliance.

94

Methods: We measured 48-hour kitchen area NO₂ concentrations at high temporal resolution in
homes of 50 intervention participants and 50 control participants longitudinally within a
biomass-to-LPG intervention trial. We also collected 48-hour mean personal exposures to NO₂
among a subsample of 16 intervention and 9 control participants. We monitored LPG and
biomass stove use continuously throughout the trial.

100

Results: In 367 post-intervention 24-hour kitchen area samples of 96 participants' homes,
geometric mean (GM) highest hourly NO₂ concentration was 138 ppb (geometric standard
deviation [GSD] 2.1) in the LPG intervention group and 450 ppb (GSD 3.1) in the biomass
control group. Post-intervention 24-hour mean NO₂ concentrations were a GM of 43 ppb (GSD
1.7) in the intervention group and 77 ppb (GSD 2.0) in the control group. Kitchen area NO₂
concentrations exceeded the WHO indoor hourly guideline an average of 1.3 hours per day
among LPG intervention participants. GM 48-hour personal exposure to NO₂ was 5 ppb (GSD

- 2.4) among 35 48-hour samples of 16 participants in the intervention group and 16 ppb (GSD
 2.3) among 21 samples of 9 participants in the control group.
- 110
- 111 **Discussion**: In a biomass-to-LPG intervention trial in Peru, kitchen area NO₂ concentrations
- were substantially lower within the LPG intervention group compared to the biomass-using
- 113 control group. However, within the LPG intervention group, 69% of 24-hour kitchen area
- samples exceeded WHO indoor annual guidelines and 47% of samples exceeded WHO indoor
- hourly guidelines. Forty-eight-hour NO₂ personal exposure was below WHO indoor annual
- 116 guidelines for most participants in the LPG intervention group, and we did not measure personal
- 117 exposure at high temporal resolution to assess exposure to cooking-related indoor concentration
- spikes. Further research is warranted to understand the potential health risks of LPG-related NO₂
- emissions and inform current campaigns which promote LPG as a clean-cooking option.

124 1. Introduction

Nearly 40% of the global population uses biomass fuels as their primary source of energy for 125 cooking.¹ Biomass cookstove emissions often result in high levels of household air pollution 126 127 (HAP), a leading environmental contributor to the global burden of disease and the cause of an estimated 1.6 million premature deaths in 2017.² Exposure to HAP has been associated with 128 increased blood pressure,^{3,4} lung cancer,^{5,6} and COPD ⁷⁻¹⁰ in adults. Women and their children 129 130 are particularly vulnerable to biomass smoke exposure due to their proximity to cooking activities in many settings.¹¹ The existing HAP literature has focused on fine particulate matter 131 (PM_{2.5}) and carbon monoxide (CO) as the components of biomass emissions which are most 132 relevant to public health.^{2,12} However, nitrogen dioxide (NO₂), an air pollutant causally related to 133 poor respiratory outcomes,¹³ has also been reported in homes with biomass cookstoves at 134 concentrations which exceed WHO indoor air quality guidelines.^{14–23} 135

136

To reduce HAP exposures and prevent HAP-related disease, most public health interventions 137 138 have focused on improved biomass cookstoves, which aim to reduce HAP exposures by improving stove combustion efficiency and/or directing stove emissions outdoors, often while 139 continuing to rely on locally available biomass fuels.²⁴ Although emissions from these improved 140 cookstoves are often lower than traditional cookstoves, concentrations and exposures from 141 improved biomass cookstoves generally remain above WHO indoor guidelines.^{25,26} More 142 recently, international campaigns ²⁷ and national governments ^{28,29} have promoted liquefied 143 petroleum gas (LPG) as a cleaner-burning alternative to biomass fuels. LPG is typically 144 transported in portable cylinders that are connected to a stove by a hose. LPG is becoming a 145 common household fuel in many urban areas of low- and middle-income countries (LMICs).³⁰ 146

These LPG stoves appear to be effective at reducing emissions of PM_{2.5} and CO ^{26,31–35} to levels
which could provide substantial public health benefits.³⁶ However, a recent study of nearly
76,000 gas and electricity users in China found lower all-cause mortality in homes with vs.
without kitchen ventilation,³⁷ suggesting that even "clean" fuels can produce health-altering
emissions. Beyond PM_{2.5} and CO, little is known about the effect of transitioning from biomass
to LPG stoves on other household air pollutants, including NO₂.

153

NO₂ is a widely regulated ambient air pollutant ^{38,39} that is considered by the United States 154 Environmental Protection Agency (US EPA) to be causally related to respiratory effects.¹³ The 155 most established health effects associated with NO₂ include pediatric asthma^{40,41} and reduced 156 lung function.^{42–49} A growing body of literature suggests associations between NO₂ exposure and 157 cardiovascular, respiratory, and all-cause mortality.^{50–52}. In high income countries (HICs), 158 159 natural gas is a common household fuel, and natural gas-burning appliances such as stoves, ovens, and heaters can be significant household sources of indoor NO₂.^{13,53–55} NO₂ 160 161 concentrations in homes with gas appliances in HICs can often meet or exceed WHO indoor annual guidelines.^{53–57} and indoor NO₂ concentrations in such homes have specifically been 162 associated with respiratory symptoms in children.⁵³ Stove quality, maintenance, design, and gas 163 fuel type (i.e. natural gas, LPG) are known to impact emissions of NO₂ from gas stoves.^{26,58} 164 However, nearly all assessments of NO_2 exposure from gas appliances have taken place in HICs. 165 Given the known elevated concentrations of indoor NO₂ from natural gas stoves in HICs and the 166 plausible differences between primary fuel type, gas stove design, function, and quality between 167 HICs and LMICs, there is a need for direct measurement of NO₂ exposures from LPG stoves in 168 169 LMIC settings. This information is critical to inform the promotion of LPG stoves as an effective

170	public health intervention. This study aims to characterize the impact of a biomass-to-LPG
171	intervention trial on kitchen area concentrations and personal exposures to NO ₂ in the Peruvian
172	Andes. As a secondary analysis to inform HAP exposure assessment strategies, we analyzed
173	between-participant versus within-participant variance across 1) two consecutive 24-hour
174	samples and 2) two 24-hour samples taken months apart during the post-intervention period.
175	
176	2. Methods
177	2.1. Study design and setting
178	We conducted a randomized controlled trial of a cleaner-cooking intervention among women
179	who used biomass cookstoves in the Peruvian Andes. The study took place in the Puno region of
180	southern Peru, bordering Lake Titicaca and located approximately 3,825 meters above sea level.
181	Puno is a rural agricultural region where subsistence farming, alpaca husbandry, and small-scale
182	quinoa and potato production are common. Study participants were enrolled from Indigenous
183	Aymara communities where Spanish and Aymara are commonly spoken. In these low-density
184	communities, homes are a median distance of 101 meters from the closest neighboring house. ⁵⁹
185	Local sources of ambient air pollution are minimal and only 4% of houses in the study area are
186	within 100 meters of an arterial road. ⁵⁹
187	
188	In the Cardiopulmonary outcomes and Household Air Pollution (CHAP) trial, ⁵⁹ 181 women

between the ages of 25 – 64 years were enrolled and randomized 1:1 into an LPG intervention
arm and a control arm. One control participant withdrew from the study after baseline

assessments, leaving an intention-to-treat sample of 180 participants. Participants in the LPG

192 intervention arm received a free, three-burner LPG cookstove (**Figure 1**) installed by trained

193 research staff, free LPG fuel delivered as needed for one year, as well as education and 194 behavioral reinforcement of exclusive LPG stove use. Participants in the control arm continued to use biomass and will receive a free LPG stove and one-year of fuel the following year. 195 196 Eligibility criteria included daily use of biomass fuels for cooking, full-time residence in their current location for at least six months, and being the primary cook for the household. Women 197 were excluded if they had hypertension, COPD, or pulmonary tuberculosis, smoked cigarettes 198 199 daily, were pregnant or planned to become pregnant within the next year, or if they planned to move out of the study area in the coming year. Demographic information was collected at 200 201 baseline via questionnaires and HAP assessments were performed at baseline and at three, six, and 12 months post-intervention. NO₂ exposure in 100 homes with biomass cookstoves using the 202 CHAP trial baseline assessments ¹⁴ and further information on the CHAP trial study design and 203 assessments has been previously published.⁵⁹ 204

205

We sampled kitchen area NO₂ concentrations during the CHAP trial's post-intervention, follow-206 207 up period in a randomized subsample of 100 participants from the larger trial (n = 180). All subsequent references to intervention and control groups refer to this subset of 100 participants. 208 Of the subset of 100 participants, 25 participants were randomly selected for additional 209 assessment of personal exposure to NO_2 . All participants gave verbal informed consent and study 210 protocols were approved by the Johns Hopkins School of Public Health Institutional Review 211 212 Board (00007128), A.B. PRISMA Ethical Institutional Committee (CE2402.16), and the Universidad Peruana Cayetano Heredia Institutional Review Board (66780). 213 214

215 2.2. Nitrogen dioxide exposure assessment

216 2.2.1. Kitchen area assessment

217	NO ₂ kitchen area concentrations were measured at one-minute resolution with direct-reading
218	instruments for a targeted 48 hours at baseline ¹⁴ and three, six, and 12 months post-intervention.
219	A randomly selected subsample of 25 kitchens was also assessed using passive time-integrated
220	samplers. Direct-reading and passive samplers (when applicable) were co-located in wire bird
221	cages and hung from the ceiling of participants' kitchens. Trained research staff used measuring
222	tapes to place monitors 1.5 meters above the floor and 1.0 meter horizontally from the edge of
223	the cookstove combustion zone, avoiding windows and doors as much as possible, to
224	approximate the breathing zone of a woman tending the fire.
225	
226	To measure kitchen area NO ₂ concentrations at high-temporal resolution, we used Aeroqual
227	Series 500 portable monitors with NO2 sensor heads (Aeroqual Limited, Auckland, New
228	Zealand). These direct-reading monitors were supported by two auxiliary batteries due to limited
229	electricity in participant homes. Every four months, we co-located all direct-reading monitors in
230	the field office to assess imprecision between devices. Using an LPG stove as a source of NO_2
231	emissions, we subjected all co-located monitors to NO2 concentrations ranging continuously
232	from background concentration to approximately 1000 ppb and back to background
233	concentration. We then estimated the median measurement from all co-located sensors at each
234	minute of the colocation. We used robust linear regression with Siegel repeated medians (mblm
235	R package v0.12.1; Komsta, 2019) to calculate intercept and slope adjustments for each sensor,
236	adjusting each sensor to the median concentration observed across the continuous range of
237	concentrations (background to approximately 1000 ppb). To determine the limit of detection
238	(LOD), two direct-reading monitors were brought to the Johns Hopkins University in Baltimore,

239	USA for co-location with a gold-standard reference instrument (model 42c, Thermo
240	Environmental Instruments Inc., Franklin, MA, USA). We defined the LOD as three times the
241	standard deviation (SD) of the difference between the device measurements and reference
242	instrument-confirmed zero-air from a dynamic gas calibrator (model 146i, Thermo
243	Environmental Instruments Inc., Franklin, MA, USA). We estimated an LOD of 20 ppb for the
244	direct-reading monitors, and 35% of all collected 1-minute measurements during the post-
245	intervention period fell beneath the LOD. All concentrations < 20 ppb were replaced with
246	LOD/sqrt(2) \approx 14.1 ppb, which is similar to a recent modeled estimate of annual ambient NO ₂
247	concentrations in the Puno region (≈ 12 ppb). ⁶⁰ We decommissioned NO ₂ sensor heads after
248	twelve months of field sampling and replaced with new, factory-calibrated sensor heads, as
249	recommended by the manufacturer for high concentration settings.
250	
251	We sampled time-integrated kitchen area NO ₂ concentrations in a subset of 25 households using

Ogawa passive samplers (Ogawa USA, Pompano Beach, FL, USA). We used standard 252 colorimetric methods ⁶¹ to analyze the passive samples at the Universidad Peruana Cayetano 253 Heredia in Lima, Peru. We measured temperature and relative humidity during each sample with 254 a collocated Enhanced Children's Monitor (RTI Inc., Research Triangle Park, NC, USA)⁶² to 255 assist in calculating final NO₂ concentrations. Temperature data for one sample was missing due 256 257 to instrument failure and was imputed using the median temperature from all kitchen samples. We took passive sampler field blanks every 10th sample and calculated the LOD as the mean plus 258 259 SD*3 concentration among blanks. We estimated an LOD of 2.6 ppb, similar to the manufacturer recommended lower range of accuracy (2 ppb). One of the passive sampler kitchen area 260 concentrations (4%) fell beneath the LOD and was replaced with LOD/sqrt(2) ≈ 1.8 ppb. 261

262

263 2.2.2. Personal exposure assessment

We assessed personal exposure to NO_2 for 48 hours among 25 participants using Ogawa passive 264 265 samplers as described previously. These badge samplers are small, lightweight, and can be easily worn by participants, in contrast to the direct-reading monitors used for kitchen area sampling 266 267 which allow for measurements at high temporal resolution but are bulkier and heavier. We altered aprons that are commonly worn by women in the study setting and attached the NO₂ 268 sampler and temperature and humidity monitors to the central chest region, to approximate each 269 270 woman's breathing zone. Field staff demonstrated how to put on and remove the device-laden 271 aprons, and requested that participants wear the aprons at all times during waking-hours and place the apron nearby when bathing or sleeping. Two personal samples had missing temperature 272 273 data, which were replaced with the median temperature among all personal samples. We used the same passive sampler LOD of 2.6 ppb for personal exposure samples, and we replaced seven 274 personal exposure samples (18%) that were below the LOD with LOD/sqrt(2) \approx 1.8 ppb. 275

276

277 2.3. Stove use monitoring

The temperature of each LPG stove was monitored every minute throughout the duration of the
study using Digit-TL temperature loggers with aluminum encasings (LabJack Corporation,
Lakewood, CO, USA). As higher stove temperatures indicate cookstove use, temperature loggers
have become an important method of directly monitoring stove use in cookstove studies, ^{63–66}
commonly referred to as Stove Use Monitors (SUMs). We suspended a temperature logger from
the middle burner of each LPG stove. To monitor biomass cookstoves, we attached temperature
loggers as close as possible to the cooking surface of the cookstove, typically within the smoke

stream and within 1.0 meters of the combustion zone. Additional information on the SUMsmethods are included as a supplement.

287

288 2.4 Statistical Methods

289 2.4.1 Analysis of nitrogen dioxide measurements

We hypothesized that mean kitchen area concentrations were highly driven by short-term 290 concentration spikes associated with a small number of cooking events per day. To avoid bias 291 from variability in the duration of samples (and the number of cooking events contained in that 292 duration), we calculated 24-hour mean concentrations for each of the two days if at least 20 293 hours of measurement data was available. Due to battery failure, 66 of 352 total direct-reading 294 samples (19%) had durations < 20 hours and were excluded from the analysis. For 64 of 352 295 296 total samples (18%) with durations between 20 and 44 hours, we used the first 24 hours to calculate 24-hour means (of which three samples had durations between 20 - 24 hours and the 297 full available duration was considered a 24-hour mean). A total of 222 of 352 samples (63%) 298 lasted >= 44 hours and two 24-hour mean concentrations were calculated (1st day and 2nd day of 299 total sample). 300

301

Because of the high-altitude setting in Puno, we assumed an altitude of 3825 MASL and conditions of 10°C to estimate an atmospheric pressure of 625 hPa and convert mass concentration WHO indoor guidelines to conditions-adjusted ppb (annual, 40 μ g/m³ = 33 ppb; hourly 200 μ g/m³ = 163 ppb).²³ We calculated hourly mean concentrations as the centered, rolling 60-minute mean during each 24-hour sample. We also calculated the proportion of time in which kitchen concentrations exceeded 163 ppb, the conditions-adjusted WHO indoor hourly

308	guideline, ²³ and derived the number of daily hours in excess of the indoor hourly guideline. We
309	calculated summary statistics for the maximum hourly mean, 24-hour mean, and daily hours in
310	excess of 163 ppb. Using the SUMs results and the direct-reading monitors, we calculated mean
311	kitchen area NO ₂ concentrations during cooking events and outside of recorded cooking events.
312	Finally, we calculated summary statistics for the time-integrated passive badge samples of
313	kitchen area concentration and personal exposure.
314	
315	2.4.2 Stove use analysis
316	We developed separate empirical algorithms to predict LPG and biomass cookstove use with
317	recorded stove temperatures from the SUMs. Additional information on statistical methods is
318	included as a supplement.
319	
320	2.4.3. Analysis of effect of LPG stove intervention on NO ₂ concentrations
321	To assess longitudinal changes in NO ₂ concentrations over the course of the 12-month post-
322	intervention period, we used a one-way ANOVA to examine marginal differences in mean
323	kitchen area concentrations between post-intervention time points within the LPG intervention
324	and control households separately.
325	
326	In baseline measurements, ¹⁴ we observed differences in kitchen area mean NO ₂ concentration
327	between treatment groups despite randomization (one-way ANOVA, mean NO ₂ concentrations
328	32 ppb lower in LPG intervention group than control group at baseline, $p = 0.04$, $N = 143$ 24-
329	hour means). To assess whether differences in post-intervention NO ₂ concentrations were
330	associated with the intervention versus the result of baseline differences between treatment

331	groups, we used linear regression to estimate the effect of the intervention on kitchen area NO ₂
332	concentrations during the entire post-intervention period, adjusting for baseline concentrations.
333	We used a single time-weighted-average (TWA) concentration for each household at each post-
334	intervention time point for this longitudinal analysis, averaging the 1 st and 2 nd day 24-hour means
335	from each sample when available (N=160 48-hour samples) and using the 1st day 24-hour mean
336	if the sample did not last long enough to provide a valid 2 nd day 24-hour mean (N=47 24-hour
337	samples).

338

339 2.4.4. Analysis of variance of 1^{st} versus 2^{nd} consecutive sampling days

We analyzed the reproducibility of 24-hour sampling by comparing consecutive 1st and 2nd day 340 mean kitchen area concentrations among all post-intervention samples that achieved two full 341 342 days of sampling (44 - 48 hours total duration). We observed heteroscedasticity in the residuals which violated model assumptions and was resolved by log-transforming NO₂ concentrations for 343 the final analysis. We performed a one-way mixed effects ANOVA assessing between-344 participant and within-participant (1st day vs 2nd day) variation in log-transformed 24-hour mean 345 kitchen area NO₂ concentration using a random intercept for the (two-day) sample. We treated 346 post-intervention samples (3, 6, 12 - month) as independent samples, and analyzed control (N = 347 76 paired samples) and LPG intervention (N = 84 paired samples) groups independently. Using 348 the results from the mixed effects ANOVA, we calculated the intraclass correlation coefficient 349 (ICC), which describes between-participant variance as a proportion of the total variance. We 350 also calculated the coefficient of variation (CV) for 1st and 2nd day samples to assess the 351 reproducibility of a one-day kitchen area NO₂ sample when compared to the subsequent day. 352

2.4.5. Analysis of variance of 1^{st} versus 2^{nd} post-intervention time points

We analyzed the reproducibility of collecting single versus multiple longitudinal NO₂ samples by 355 exploring within-participant versus between-participant variance of kitchen area samples taken 356 357 months apart during the post-intervention period. We included in the analysis the first two valid samples from the post-intervention period for each participant. We used only the 1st day 24-hour 358 mean from each 48-hour sample to improve the comparison with results from the 1st day vs 2nd 359 consecutive day variance analysis (Section 2.4.4.). We log-transformed 24-hour mean NO₂ 360 concentrations to comply with model assumptions of homoscedasticity of residuals. In our final 361 362 model, we conducted a one-way mixed effects ANOVA with a random intercept for household, analyzing intervention and control groups independently and calculating the ICC for between-363 household variance. Additionally, we calculated the treatment group-specific coefficient of 364 variation for 1st and 2nd post-intervention samples to quantify the reproducibility of kitchen area 365 NO₂ samples taken longitudinally throughout the post-intervention period of the trial. All 366 analyses were performed using R (www.r-project.org). 367

368

369 *3. Results*

370 *3.1 Participant characteristics*

We sampled kitchen area NO₂ concentrations using direct-reading monitors among 49 participants in the LPG intervention group and 47 participants in the control group (total N=96 participants). Due to battery failures, four participants (4% of N=100) did not have any postintervention samples reaching the minimum duration (20 hours) and were excluded from the analysis. The mean age among all participants in the NO₂ assessment was 48.2 years and 59% of participants had a primary school education or less (**Table 1**). Ninety-three percent of

377 participants were in the lowest two quintiles of socio-economic status in Peru. Only 6% of intervention participants' kitchens had a chimney, while 67% had an opening in the roof above 378 the biomass cookstove and 27% had no specific cookstove ventilation. This differed somewhat 379 380 from control participants, who had more chimneys (13%), fewer roof openings (38%), and more homes with no cookstove ventilation (49%). Typical kitchens among study participants had roofs 381 of corrugated metal or natural fiber, walls of adobe or mud, and earth floors. Many kitchens had 382 no windows (40%), while 44% of kitchens had one window and 17% of kitchens had two or 383 more windows. Using the SUMs which monitored both LPG and biomass cookstoves 384 385 continuously in all participants' homes, we estimated that women in the LPG intervention group used their LPG stoves exclusively in 98% of monitored days. 386 387 388 *3.2. Post-intervention kitchen area nitrogen dioxide concentrations* During the post-intervention period and using direct-reading monitors, we successfully collected 389 367 24-hour mean kitchen area concentrations from 207 samples (20-48 hours duration) 390 391 representing a total of 96 unique households from the intervention and control groups. We observed a geometric mean (GM) 24-hour kitchen area NO₂ concentration of 43 ppb (geometric 392 393 standard deviation [GSD] 1.7) in the LPG intervention group during the post-intervention period, 30% higher than the WHO indoor annual guideline of 33 ppb (**Table 2**). Sixty-nine percent of 394 LPG intervention kitchen samples had 24-hour mean concentrations that exceeded the WHO 395 396 indoor annual guideline. In control kitchens, the GM 24-hour kitchen area concentration during the post-intervention period was 77 ppb (GSD 2.0). Kitchen area NO₂ concentrations exceeded 397 the WHO indoor hourly guideline for a mean of 1.3 hours per day in intervention households and 398 399 2.5 hours per day in control households. We observed a GM kitchen concentration of 91 ppb

400 (GSD 2.1) during LPG cooking events in the intervention group, compared to a GM concentration of 33 ppb (GSD 1.8) outside of LPG cooking events (though the mean 401 concentration outside of cooking events includes time directly after cooking events ended, when 402 NO₂ concentrations likely remained elevated before decaying to background levels). In control 403 404 households, GM kitchen area concentrations were 296 ppb (GSD 2.8) during biomass cooking 405 events and 39 ppb (GSD 2.0) outside of recorded cooking events. A subset of participants 406 received additional kitchen area sampling of 48-hour time-weighted average concentration via 407 passive samplers. Among 37 post-intervention samples from 16 unique participants in the LPG 408 intervention group, we observed a GM 48-hour mean kitchen area concentration of 29 ppb (GSD 2.2). In the control group, we observed a GM 48-hour kitchen area mean of 99 ppb (GSD 4.3) in 409 410 21 post-intervention samples from 9 unique participants (Table 2).

411

We observed acute spikes in NO₂ kitchen area concentrations during common cooking times 412 among participants in both the intervention and control groups. We present these data as a bar 413 plot of kitchen area concentrations throughout each minute of the calendar day (Figure 2) from 414 415 all post-intervention samples. Dark blue indicates the proportion of households with kitchen area 416 NO_2 concentrations ≤ 32 ppb at a given time of day, with increasingly higher concentrations represented by other colors as described in the legend. A substantial proportion of kitchens in the 417 LPG intervention group (Figure 2, top panel) experience NO₂ concentrations exceeding WHO 418 419 indoor guidelines (annual 33 ppb, hourly 163 ppb) during common cooking times (05:00-09:00 and 18:00-20:00 hours). For example, at approximately 08:00 hours, NO₂ concentrations were > 420 421 250 ppb in 15% of households (red color), \geq 163 ppb (the WHO indoor hourly guideline) in 25% 422 of households (red and orange colors), and ≥ 66 ppb in 55% of households (red, orange, and

423	yellow colors). In the corresponding figure of NO ₂ concentrations in biomass cookstoves
424	(Figure 2, bottom panel), concentrations are elevated during the same common cooking hours,
425	but peaks are at higher concentrations in biomass homes than in LPG homes. The GM highest
426	hourly concentration during each 24-hour sample was 138 ppb (GSD 2.1) in LPG intervention
427	homes and 450 ppb (GSD 3.1) in biomass control households (Table 2). We present the
428	distribution of highest hourly means in the intervention and control groups as a modified
429	empirical distribution function plot (Figure 3), with the WHO indoor hourly guideline as a
430	reference. The X-axis represents NO ₂ concentration and the Y-axis represents the percent of 24-
431	hour samples with a maximum hourly-average concentration less than the corresponding
432	concentration. During the intervention period 47% of 24-hour samples in the LPG intervention
433	group and 81% of 24-hour samples in the biomass control group had hourly means exceeding the
434	WHO indoor hourly guideline.

435

436 *3.3. Personal exposure to nitrogen dioxide*

Among 35 samples from 16 unique participants in the LPG intervention group, we observed a 48-hour mean NO₂ personal exposure of 8 ppb (SD 11 ppb) with a GM of 5 ppb (GSD 2.4). We observed a mean of 23 ppb (SD 24 ppb) and a geometric mean of 16 ppb (geometric SD 2.3 ppb) 48-hour personal exposure among 21 samples from 9 participants in the control group. Three percent (N = 1 of 35) of personal exposure samples from women in the LPG intervention group and 19% (N = 4 of 21) of personal exposure samples in the control group had 48-hour timeintegrated personal exposures in excess of the WHO indoor annual guideline of 33 ppb.

444

445 *3.4. Longitudinal effect of LPG intervention on NO₂ exposures*

446	In Figure 4, kitchen area 24-hour means are presented from baseline through the end of the post-
447	intervention period, with lines indicating treatment group means at each time point, points
448	representing individual 24-hour mean concentrations, and the WHO indoor annual guideline
449	added for reference. Using a one-way ANOVA, we found no evidence of longitudinal
450	differences in group means across post-intervention time points in either 179 24-hour means
451	from 49 participants in the LPG intervention group (p-value = 0.09) or 188 24-hour means from
452	47 participants in the control group (p-value = 0.99).
453	
454	Because baseline kitchen area concentrations were lower in the LPG intervention group, we used

linear regression to estimate the effect of treatment group on post-intervention kitchen area NO₂,
adjusting for baseline concentration (Section 2.4.3.). We estimate that among 79 participants
with baseline and post-intervention samples, being in the LPG intervention group was associated
with a 45 ppb lower (95% CI -59 to -31) post-intervention daily mean kitchen area concentration
when compared to the control group.

460

461 3.5. Between- and within- variation among 1^{st} versus 2^{nd} consecutive sampling days

We examined between-participant versus within-participant variance among kitchen area 24hour means on the 1st versus 2nd consecutive days of sampling (Section 2.4.4.). In both the LPG intervention and control groups, we found greater variance between households than within households, however the reproducibility of sampling within a household on consecutive days was somewhat poor. Within 76 paired samples (1st and 2nd consecutive days) in the LPG intervention group we observed an intraclass correlation coefficient (ICC) of 0.68, indicating that 68% of the total variance was between households while 32% of total variance was within

469	households (Table 3). Similarly, we found that 73% of variance was between households (ICC
470	0.73) with a CV of 35% in 84 paired samples of the biomass control group.

471

3.6. Between- and within- variation among 1^{st} versus 2^{nd} post-intervention time points 472 We also compared kitchen area NO₂ concentrations from longitudinal samples taken months 473 apart during the post-intervention period (Section 2.4.5.). In the LPG intervention group, we 474 observed an ICC of 0.14 among 38 sample pairs (1st and 2nd available post-intervention time 475 points), indicating more variance within a given household across time (86% of total variance) 476 477 than between different households (14% of total variance). Within the same group we estimated a CV of 49%, suggesting poor reproducibility within participants over time. In the control group 478 of 38 sample pairs, the ICC was 0.57 with a CV of 52%, suggesting a more equal balance of 479 480 between/within variance but similarly poor reproducibility across the post-intervention period.

481

482 *4. Discussion*

483 This study is the first study that the authors are aware of to measure kitchen area concentrations of NO₂ at high-temporal resolution or personal exposure to NO₂ from LPG stoves in an LMIC 484 field setting. We observed substantial reductions in kitchen area concentration and personal 485 exposure to NO₂ in a biomass-to-LPG intervention. While lower than biomass control 486 households, in the LPG intervention group, we observed large concentrations spikes of kitchen 487 area NO₂ concentrations during common cooking times. In the LPG intervention group, 69% of 488 24-hour samples exceeded the WHO indoor annual guideline and 47% of samples exceeded the 489 WHO indoor hourly guideline. Participants in the LPG intervention group experienced a mean of 490 491 1.3 hours per day (SD 1.6 hours) of kitchen area NO_2 concentrations above the WHO indoor

hourly guideline. GM 24-hour average kitchen area concentrations were 1.3 times higher than
the WHO indoor annual guideline (163 ppb) in the LPG intervention group and 2.3 times higher
in the biomass control group. However, GM 48-hour mean personal exposure was well below
WHO indoor annual guidelines in the LPG intervention group.

496

Among homes using LPG stoves, we observed an arithmetic mean 24-hour kitchen area NO₂ 497 concentration of 49 ppb (SD 26 ppb) using direct-reading monitors and 38 ppb (SD 29 ppb) in a 498 subset of homes using passive samplers. These values are similar to a arithmetic mean of 38 ppb 499 NO₂ reported by Padhi et al. among 24-hour samples of kitchens with LPG stoves in India.²⁰ 500 501 While assessments of NO₂ exposures from LPG stoves in LMIC settings are sparse, a few other studies have reported NO₂ concentrations in kitchens with natural gas or non-specific "gas 502 503 stoves". A study of kitchens with gas stoves in Bangladesh reported a 24-hour geometric mean kitchen area NO₂ concentration of 84 ppb,¹⁷ though the specific type of gas fuel (i.e. natural gas, 504 LPG, other) was not reported. Colbeck et al. observed 1-week mean NO₂ concentrations in 505 506 kitchens with natural gas stoves in Pakistan of 129 ppb in the winter when windows are kept closed and 43 ppb in the summer when windows are open,¹⁸ suggesting that ventilation may be 507 an important and actionable predictor of indoor NO₂ concentrations in homes with gas stoves. 508 This was corroborated on a smaller magnitude among LPG intervention participants in our study, 509 in which mean kitchen area concentrations were 52 ppb (SD 29 ppb, N = 53 24-hour samples) in 510 511 winter and 45 ppb (SD 20 ppb, N = 27 24-hour samples) in summer.

512

513 The relative NO₂ emissions of LPG stoves vs natural gas stoves in LMIC field settings is poorly 514 understood, and other factors which have major impacts on area concentrations, including stove

515 burner design, individual cooking behaviors, and kitchen size and ventilation are rarely available 516 in the current literature. In a seminal review of NO_2 exposures from gas stoves in HICs, where overall stove quality is potentially higher than in many LMIC settings, use of a gas stove 517 518 increased mean indoor NO₂ by 15 ppb compared to homes with electric stoves. In this review, an equivalent 15 ppb increase in indoor area NO₂ concentration corresponded with an odds ratio of 519 1.18 for lower respiratory tract illnesses in children.⁵³ In homes with LPG stoves in Puno, we 520 observed a GM 24-hour kitchen area NO₂ concentration of 43 ppb in the LPG intervention 521 group, 10 ppb higher than the WHO indoor annual guideline of 33 ppb. We also observed 522 523 concentration spikes that commonly exceeded 500 ppb and a mean maximum hourly mean kitchen area concentration of 178 ppb (WHO indoor hourly guideline: 163 ppb). Concentration 524 spikes on this order of magnitude have been reported previously in homes with gas appliances in 525 526 HICs. For example, a field study of children in Australian homes with gas stoves found 1-hour mean personal exposures of greater than 200 ppb during periods of gas stove use.⁶⁷ 527

528

529 We assessed the between-participant vs within-participant variance of measuring kitchen area NO₂ on two consecutive days during the post-intervention period. We found greater between-530 participant variance than within-participant variance, suggesting that limited sampling resources 531 may be more efficiently directed towards sampling a larger number of participants for 24-hours 532 than fewer participants for 48-hours. However, 24-hour kitchen area NO₂ samples had poor 533 reproducibility on consecutive days, and the limitations of a 24-hour kitchen area samples should 534 be considered when designing studies which are focused on individual-level health outcomes, 535 where personal exposure levels are more relevant. 536

538 We also analyzed the between-participant vs within-participant variance of kitchen area NO₂ 539 measurements taken months apart during the post-intervention period. Compared to the analysis of samples on subsequent days, we found more within-participant variability among samples 540 541 taken months apart, which may be related to seasonality. Within-participant variability was similar between the LPG intervention and biomass control groups, but between-participant 542 543 variability was substantially lower in the LPG group (16% of total variance). This could be explained by more similarity in emissions from LPG stoves than biomass stoves due to 544 standardization of the stoves and fuel, which were provided to participants in the intervention 545 546 trial. In contrast, biomass stoves are often homemade and can use a variety of biomass fuel types. It may be that given a standardized LPG intervention, a relatively small number of participants 547 are needed to reasonably assess NO₂ kitchen area concentrations in the group longitudinally, 548 549 though likely only in settings where other emissions-related factors such as kitchen ventilation are also consistent. It is worth noting that in this intervention trial, we observed 98% exclusive 550 adoption of LPG stoves and consistency in NO₂ concentrations longitudinally across post-551 552 intervention samples, and it is highly unlikely that the observed levels of NO_2 are due to 553 continued use of biomass stoves in the LPG intervention arm.

554

This study is strengthened by its use of direct-reading monitors, which allowed us to characterize concentration spikes associated with LPG cooking and compare kitchen area concentrations with WHO indoor hourly air quality guidelines, which have not been previously reported. By deploying stove use monitors, we were also able to co-monitor stove use and kitchen area NO₂ concentration to estimate concentrations during cooking events and the duration of time per day spent above WHO indoor guidelines. We also measured 48-hour mean personal exposure to NO₂

561 among a subsample of LPG and biomass users, which is a novel contribution to the field. This 562 study was further strengthened by the use of longitudinal measurements throughout a cleanercooking intervention with a one-year follow-up period. This study is limited by a lack of 563 measurements of hourly or peak personal exposure to NO₂, due to the burden of asking 564 participants to carry NO₂ direct-reading monitors. Based on the observed high concentration 565 566 spikes of kitchen area NO₂ concentrations during cooking and studies in HICs, we believe the greatest risk of exposure to NO₂ for people who use LPG stoves are concentration spikes as 567 opposed to mean NO_2 concentrations. While many women in our setting may not spend the 568 569 entire duration of a cooking event in the kitchen area, the peak personal exposures of women in our setting may in fact be comparable to the concentration spikes observed in the kitchen areas 570 when they are actively cooking. However, 48-hour mean personal exposures to NO₂ were well 571 572 below WHO indoor annual guidelines for most participants in the LPG intervention group. Future research is warranted to characterize personal exposure to LPG stove-related NO₂ 573 concentration spikes, assess personal exposure among children who are especially vulnerable to 574 NO_2 exposure, and to compare NO_2 exposures in households with LPG stoves to households 575 with electric stoves in LMICs. 576

577

578 *5. Conclusions*

In a biomass-to-LPG intervention trial in the Peruvian Andes, we observed substantially lower
NO₂ kitchen area concentrations and personal exposures among participants in the LPG
intervention. However, within LPG intervention households, 69% of 24-hour samples of kitchen
area concentration exceeded WHO indoor annual guidelines and 47% of samples exceeded

583	WHO indoor hourly guidelines. Among a subsample of participants, GM 48-hour personal
584	exposure was well below WHO indoor annual guidelines in the LPG intervention group.
585	
586	While measurements of NO ₂ concentrations from LPG stoves are sparse in LMICs, these results
587	are not unexpected given previous assessments of NO2 in kitchens with gas stoves in LMICs and
588	the growing body of literature on the health impacts of NO ₂ exposures from gas stoves in HICs.
589	As the global community considers the promotion of LPG and other gas stoves as cleaner-
590	burning alternatives to biomass based on reductions in PM _{2.5} and CO, exposures to NO ₂ emitted
591	by LPG stoves may persist at levels that pose a risk to health. In settings where LPG stoves are
592	currently being used or use of electric stoves is still far off, the ability of actionable factors such
593	as ventilation and stove design to mitigate NO2 exposures should be explored further and
594	incorporated into LPG promotion campaigns.

- samples from 49 houses in the intervention group and 188 24-hour samples from 47 houses in
- 11 the control group of a biomass-to-LPG cleaner-cooking trial in Puno, Peru.
- 12 Figure 3. Cumulative distributions of the highest hourly mean NO₂ concentrations in 367 24-
- 13 hour samples of 96 kitchen areas, comparing intervention and control groups during the follow-
- 14 up period of a biomass-to-LPG intervention trial in Puno, Peru.
- 15 Figure 4. Longitudinal changes in kitchen area 24-hour mean NO₂ concentrations among
- 16 intervention and control groups in an LPG intervention trial. Lines indicate mean kitchen area
- 17 NO₂ concentrations at each time point for the intervention and control groups. Points represent
- 18 NO₂ 24-hour mean concentration from 367 samples in 96 unique households. The Y-axis
- 19 representing NO₂ ppb is log-scaled. Altitude- and temperature-adjusted WHO indoor air quality
- 20 guideline for annual mean NO_2 (33 ppb) presented as a reference.

22	A 1.
22	Appendix
23	
24	Statistical methods for analysis of stove temperature monitors
25	
26	We developed separate empirical algorithms to predict LPG and biomass cookstove use with
27	recorded stove temperatures. To identify LPG stove use, we considered an LPG cooking event to
28	begin at time t when the 20-minute rolling mean temperature at time $t + 5$ minutes was at least
29	10 % greater than at $t - 5$ minutes (depicted in Appendix Figure 1). A cooking event stopped
30	when the 20-minute rolling mean temperature dropped 3°C below the maximum 20-minute
31	rolling mean temperature in the cooking event. For biomass cookstoves, we considered a
32	cookstove usage event to begin at time t when the 30-minute rolling mean temperature at time t
33	+ 30 minutes was 2°C greater than at t. A cooking event stopped when the 30-minute rolling
34	mean temperature dropped 2°C below the maximum 30-minute rolling mean temperature in the
35	cooking event. For both types of cookstove, we made a priori assumptions based on formative
36	research that multiple cooking events within a 60-minute period were considered one cooking
37	event, an individual cooking event cannot last more than four hours for an LPG stove or six
38	hours for a biomass cookstove, and the rolling mean must exceed 20°C at some point during a
39	cooking event. To assess the validity of the SUMs algorithms, an independent researcher not
40	involved in the creation of the algorithm manually evaluated a 5-day random sample of SUMs
41	data from each stove in each household in CHAP (N=180 households). Manual observations and
42	algorithm estimates were in agreement on whether stove use had occurred in 95% of 787 days of
43	monitored biomass cookstoves and in 99.7% of 762 days of monitored LPG stoves.
44	

- 46 Appendix Figure 1. Empirical algorithm for identifying LPG stove use from stove temperature
- 47 logged throughout the duration of the study at one-minute intervals. A similar algorithm exists
- 48 for biomass cookstoves (not shown).
