25 NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

26 **ABSTRACT**

27 **Background:** Clinical diagnosis of COVID-19 poses an enormous challenge to early
28 detection and prevention of COVID-19, which is of crucial importance for pandemic
29 containment. Cases of COVID-19 may be hard to distinguish clinically from other acute
30 viral diseases, resulting in an overwhelming load of laboratory screening. Sudden
31 onset of taste and smell loss emerge as hallmark of COVID-19. The optimal ways for
32 including these symptoms in the screening of suspected COVID-19 patients should
33 now be established.

34 **Methods:** We performed a case-control study on patients that were PCR-tested for
35 COVID-19 (112 positive and 112 negative participants), recruited during the first wave
36 (March 2020 – May 2020) of COVID-19 pandemic in Israel. Patients were interviewed
37 by phone regarding their symptoms and medical history and were asked to rate their
38 olfactory and gustatory ability before and during their illness on a 1-10 scale.
39 Prevalence and degrees of symptoms were calculated, and odds ratios were
40 estimated. Symptoms-based logistic-regression classifiers were constructed and
41 evaluated on a hold-out set.

42 **Results:** Changes in smell and taste occurred in 68% (95% CI 60%-76%) and 72% (64%-
43 80%), of positive patients, with 24 (11-53 range) and 12 (6-23) respective odds ratios.
44 The ability to smell was decreased by 0.5 ± 1.5 in negatives, and by 4.5 ± 3.6 in
45 positives, and to taste by 0.4 ± 1.5 and 4.9 ± 3.8 , respectively (mean \pm SD). A penalized
46 logistic regression classifier based on 5 symptoms (degree of smell change, muscle
47 ache, lack of appetite, fever, and a negatively contributing sore throat), has 66%
48 sensitivity, 97% specificity and an area under the ROC curve of 0.83 (AUC) on a hold-
49 out set. A classifier based on degree of smell change only is almost as good, with 66%

50 sensitivity, 97% specificity and 0.81 AUC. Under the assumption of 8% positives among
51 those tested, the predictive positive value (PPV) of this classifier is 0.68 and negative
52 predictive value (NPV) is 0.97.

53 **Conclusions:** Self-reported quantitative olfactory changes, either alone or combined
54 with other symptoms, provide a specific and powerful tool for clinical diagnosis of
55 COVID-19. The applicability of this tool for prioritizing COVID-19 laboratory testing is
56 facilitated by a simple calculator presented here.

60 dysfunction, gustatory dysfunction, classifier, screening, rating

61 **BACKGROUND**

62 In December 2019, the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-
63 2) was reported in Wuhan, China[1]. The resulting coronavirus disease COVID-19 has
64 become a global pandemic with 16.5 million reported cases as of July 29th, 2020
65 (World Health Organization, 2020). When assessing SARS-CoV-2 infection, clinicians
66 initially focused on the most common symptoms at the onset of COVID-19 illness such
67 as fever, cough, and fatigue. Other reported signs and symptoms included sputum
68 production, headache, hemoptysis, diarrhea, and dyspnea [2].

69 Since March 2020, an increasing number of reports regarding taste and smell loss in
70 COVID-19 infections appeared in preprints[3, 4] and in general press, and it is currently
71 well established that taste and smell loss is common in COVID-19 patients[5–8].

72 Earlier studies have already suggested associations between anosmia (loss of smell)
73 and the coronavirus causing Severe Acute Respiratory Syndrome (SARS), SARS-CoV-1.
74 Olfactory symptoms[9] and taste disorders[10] have also been associated also with
75 viral upper respiratory tract infections caused by other viruses, as well. However, the
76 prevalence of olfactory loss in COVID-19 is usually reported as much higher[11–15]
77 than in other diseases[16]. In a recent crowd-sourced study, ~7000 app users reported
78 testing positive for COVID-19, with 65% of those reporting that they lost their sense
79 of smell or taste[14], a three-fold increase in prevalence compared to COVID-19
80 negatives[17]. The severity of smell and taste loss in COVID-19 patients is striking:
81 these sensory abilities were reduced by -79.7 ± 28.7 , -69.0 ± 32.6 (mean \pm SD),
82 respectively, as reported by about 4000 participants using a 0-100 visual analog scale
83 (VAS)[7]. A follow-up study found that recent smell loss is the best predictor for COVID-
84 19[18].

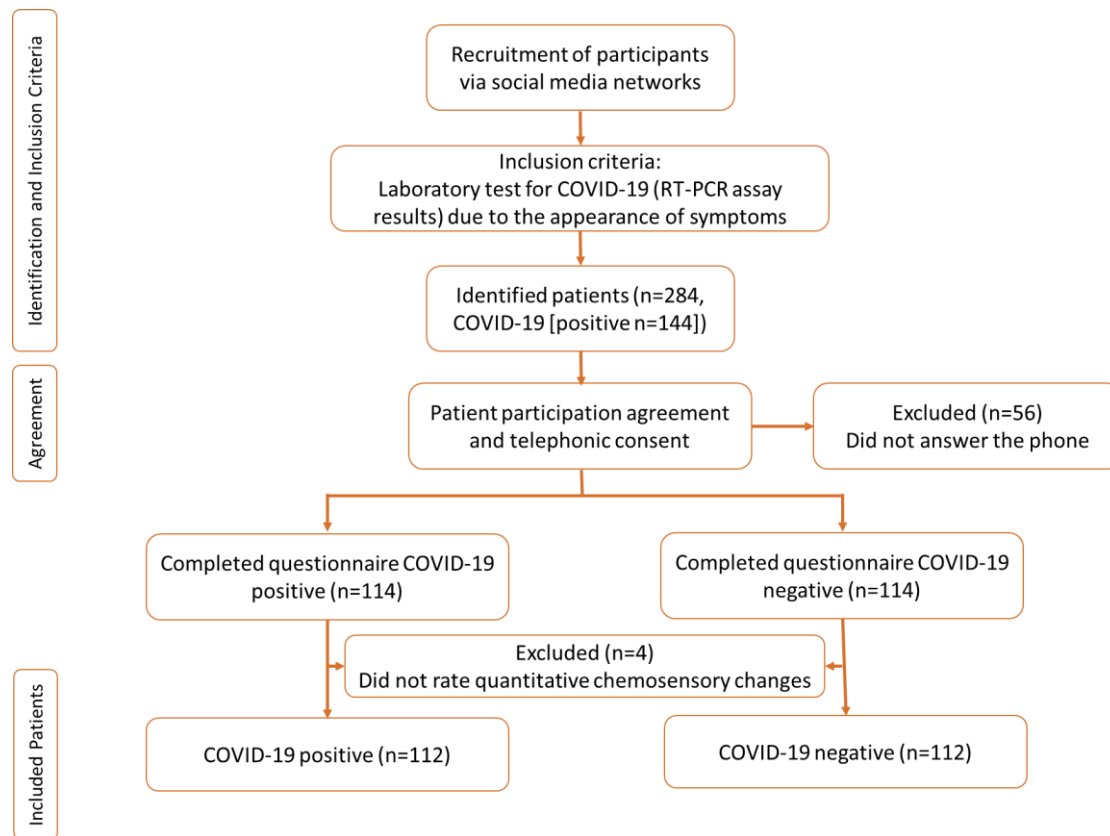

85 Here we assess the prevalence of different COVID-19 symptoms as well as the degree
86 and additional characteristics of smell and taste changes in PCR-swab tested COVID-
87 19 positive vs COVID-19 negative patients. Importantly, patients were recruited in a
88 manner that did not disclose the underlying chemosensory questions in this study. We
89 used these data to develop a classifier that can prioritize patients for PCR-testing, help
90 epidemiological investigations, and screen large populations.

91

92 **METHODS**

93 **Aim and setting**

94 This prospective study compared symptoms in real time (RT) polymerase chain
95 reaction (PCR)-tested COVID-19 positive and COVID-19 negative patients. Patients
96 having PCR-test results (positive or negative) were recruited via social media (Twitter
97 and Facebook) and word of mouth from March 2020 to May 2020 and interviewed
98 from April 2020 to June 2020. The cohort comprised 224 Israeli patients aged ≥ 18
99 years (Figure 1) Israeli patients. The participants were not aware that the
100 questionnaire will include smell and taste loss symptoms prior to their agreement to
101 partake in the study. Informed consent was obtained from all participants. The study
102 was approved by the Hadassah Medical Center Helsinki Committee (permit number
103 0236-20-HMO).

104

105 **Figure 1. Flow chart of patients' selection for case control study.**

106

107 **General design**

108 The interviews were carried out over the phone. The questionnaire is based on
109 questions compiled by physicians and scientists in the Global Consortium for
110 Chemosensory Research, GCCR[7]. The full questionnaire is included in
111 Supplementary data and has five parts: 1) General information (e.g., age, gender); 2)
112 Medical history (e.g., medical conditions, medications, changes in taste/smell in the
113 past, pregnancy, contact with a confirmed patient); 3) Current illness: 23 physical signs
114 and symptoms, including binary question (yes/no) on smell, taste and chemesthesis
115 (cooling, burning, tingling sensation), PCR swab test results and dates, date of
116 exposure to confirmed COVID-19 patient, subjective recovery feeling; 4) Smell:
117 Participants were instructed to rate their sense of smell/ taste and the degree of their

118 nose blockage on a scale from 1-10 (1 corresponding to “no sense of smell” and 10 to
119 excellent sense of smell) and similarly rate the ability to breathe through the nose
120 before/during/after illness. Blocked nose rating was used to test the plausible
121 hypothesis that it causes a change of smell; 5) Taste (e.g., rating of taste ability
122 before/during/after illness, as described for smell), experience of strange/bad taste in
123 the mouth, change in sensitivity to irritants (chemesthesis) and change in basic taste
124 modalities – sweet, salty, sour, bitter, each elicited by non-volatile compounds via
125 specific receptors or channels expressed in dedicated taste receptor cells [19]. The
126 fifth basic taste modality, umami or savory, was not used because it does not have a
127 Hebrew translation. “Other” taste was available as an additional optional answer. Data
128 was kept in Compusense Cloud on-line software (Compusense Inc., Guelph, ON,
129 Canada).

130

131 **Statistical analysis**

132 Log-odds for the individual symptoms were calculated over the full dataset.
133 Confidence intervals and p-values for the log-odds were estimated from the *glm*
134 function using the logistic link implemented in the statistical software R
135 (<https://www.r-project.org/>).

136 Classifiers were trained from the reported symptoms to evaluate the
137 separation between COVID-19 positive and COVID-19 negative patients. The classifiers
138 were trained on a random subset of 2/3 of the data (the training set, 148 samples),
139 and evaluated on the remaining samples (the test set). Sampling of the train and test
140 sets was stratified by COVID-19 status. We trained the classifier on the full symptom
141 matrix: All symptoms of question 23 in the questionnaire (see Supplementary) were

142 included, except "no symptoms" or "other". All eye symptoms were combined to "Eye
143 symptoms". Also added were quantitative questions for taste, smell, and nose
144 blockage (rating before the illness minus rating during the illness, questions 31, 35, 37,
145 38, 40, 41 in the questionnaire) and chemesthesis (question 45) "Coated tongue",
146 "Dizziness", "Ears pressure", "Eye burn", "Eye discharge", "Hearing change",
147 "Lacrimation", and "Vision changes" were removed since these symptoms were
148 reported by less than 10% of the subjects. The classifiers were trained as penalized
149 logistic regressions, using the elastic net algorithm ($\alpha = 0.5$ implemented in the *glmnet*
150 package in the R environment. This regression method encourages sparse coefficient
151 vectors, meaning that it is suitable in situations where only few coefficients are non-
152 zero. The regularization parameter (λ) was initially set using cross-validation,
153 but then increased until the model included no more than six symptoms. For classifiers
154 based on a single symptom, no regularization was used.

155 Classifiers were evaluated using the hold-out test set. The score from the
156 classifier was thresholded at zero, so that patients with score exceeding 0 were called
157 positive by the classifier. Sensitivity (predicting COVID-19 positives correctly) and
158 specificity (predicting COVID-19 negatives correctly) metrics were calculated from the
159 following formulas:

$$160 \quad \text{Sensitivity} = \frac{TP}{TP + FN}, \quad \text{Specificity} = \frac{TN}{TN + FP}$$

161 in which TP (TN) are the COVID-19 positives (negatives) classified correctly, and FN
162 (FP) are the COVID-19 positives (negatives) classified incorrectly. Due to our balanced
163 sample, accuracy is the average of sensitivity and specificity. We further computed the
164 accuracy metrics that account for the expected proportion of positive cases in the
165 tested population, namely the positive predictive value (PPV) and the negative

166 predictive value (NPV). The scores obtained from the logistic classifier (s) were
167 translated into probability to be positive (P) by adjusting for the proportion of COVID+
168 out of the tests (π) according to the following formulas:

$$169 \quad o = \frac{P(+|Symptoms)}{P(-|Symptoms)} = \exp(s) * \frac{\pi}{1 - \pi}$$

$$170 \quad P = \text{Probability to be positive} = \frac{o}{o + 1}$$

171 We take π to be 0.08 because that was the proportion during data collection.

172 The ROC curve corresponds to true-positive and false-positive rates for different
173 values of the threshold; the curve and the area under the ROC curve (AUC), which
174 measures the degree of separability between positive and negative scores, were
175 estimated using the *pROC* package[20].

176

177 **Sample size calculation**

178 The sample size was calculated to allow detecting differences in smell-loss or taste-
179 loss prevalence between COVID-19 positive and negative populations. Based on
180 previous research [e.g. [21]], we used conservative estimates of 60% prevalence in the
181 positive population and 35% prevalence in the negative population. Power was
182 estimated by Monte Carlo simulations, namely repeatedly ($b=1000$) resampling from
183 two Binomial distributions corresponding to the positive population and the negative
184 population. Assuming 100 individuals are assigned to each group, and a two-sided t-
185 test is used, the probability of detection (power) is 92%. To be on the conservative
186 side, we used somewhat larger samples.

187

188 **RESULTS:**

189 **Patients' characteristics**

190 Completed questionnaires were obtained from 112 COVID-19 positives and 112
191 COVID-19 negatives. The median age of the respondents was 35 ± 12 years for

192 positives and 37 ± 12 years for negatives (mean \pm SD) years. The positives group
193 included more men (64%), while the negatives group was more balanced (48% males).
194 Seven patients classified as hospitalized (received respiratory support during their
195 hospitalization and / or were hospitalized in the intensive care unit) and the rest 217
196 were classified as ambulatory patients.

197

198 Patients' symptoms

199 Signs and symptoms that appeared in the binary part of the questionnaire
200 (Supplementary Material, question 23 of the full questionnaire) and were found to
201 occur in at least 10% of the positive patients are summarized in Table 1. A few
202 symptoms, including dry cough and sore throat, were prevalent in COVID-19 positives,
203 but even more so in the negatives control sample.

204 Smell change, taste change, change in chemesthetic ability (perceiving spicy, tingling
205 or cooling sensations) and muscle ache were significantly more prevalent in COVID-19
206 positive as compared to COVID-19 negative patients (68%, 72%, 31%, 62% vs. 8.0%,
207 18%, 6%, 34%, respectively) (Table 1). Other CDC recognized symptoms[22], such as
208 lack of appetite, fever, and diarrhea were approximately twice or three times more
209 common among positives than negatives.

210

211 **Table 1. Prevalence and odds ratios of signs and symptoms.** Only signs and symptoms
212 that were present in at least 10% of all study participants are listed. Those with the
213 highest odds ratios are shown in red and those reported by at least a third of positives
214 are shown in boldface.

	Positives (%)	Negatives (%)	P-value	Estimated OR (Lower bound, Upper bound)
Smell change	68	8	<0.0001	24.16 (10.98, 53.14)
Taste change	72	18	<0.0001	12.02 (6.36, 22.72)
Chemesthesis	31	6	<0.0001	6.82 (2.88, 16.16)
Muscle ache	62	34	<0.0001	3.25 (1.88, 5.61)
Lack of appetite	53	27	<0.0001	3.04 (1.74, 5.32)
Fever	65	41	<0.0001	2.69 (1.56, 4.61)
Diarrhea	24	12	0.01	2.42 (1.17, 4.98)
Abdominal pain	21	11	0.03	2.27 (1.07, 4.81)
Nausea or vomiting	21	12	0.07	1.97 (0.94, 4.12)
Eye symptoms	21	12	0.1	1.81 (0.88, 3.73)

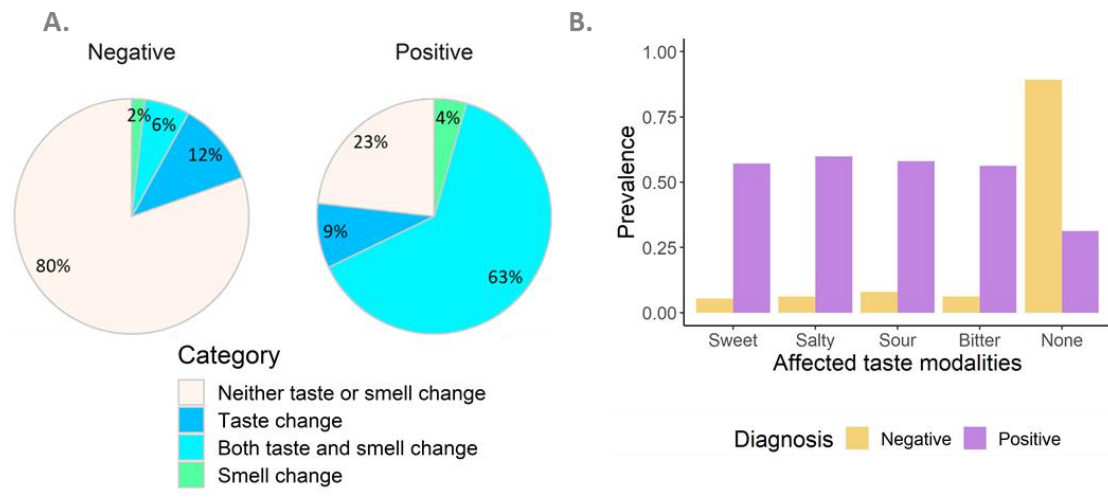

Headache	62	49	0.06	1.66 (0.98, 2.83)
Productive cough	46	40	0.4	1.24 (0.73, 2.12)
Bad taste in mouth	17	14	0.6	1.23 (0.59, 2.53)
Runny nose	38	39	0.9	0.96 (0.56, 1.65)
Fatigue	18	21	0.6	0.84 (0.43, 1.64)
Chest pain	23	28	0.5	0.79 (0.43, 1.44)
Voice change	13	18	0.4	0.71 (0.34, 1.47)
Dry cough	62	71	0.2	0.67 (0.38, 1.17)
Sore throat	37	56	<0.0001	0.45 (0.26, 0.77)
Breath difficulty	21	38	<0.0001	0.43 (0.24, 0.78)

215 * burning, cooling or tingling sensation

216

217 Nausea or vomiting, although considered a COVID-19 symptom, were not more
 218 common among COVID-19 positive as compared to COVID-19 negative patients. By
 219 contrast, lack of appetite, despite not being included as an "official" CDC
 220 symptom[22], was found to be significantly more common in COVID-19 positive
 221 patients.

222 Taste and smell change often, but not always, together: Figure 2A shows the
 223 distribution of reports on taste and smell changes. Change in both smell and taste
 224 perception was reported by 63% of positive patients and only 6% of negative patients.
 225 4% of positive patients experienced only smell change and 9% reported taste change
 226 with no smell change.

227

228 **Figure 2. Smell, taste, and taste modalities changes during disease.** A. The pie chart presents
229 prevalence of smell and taste changes in positive and negative patients, occurring together or
230 separately. Numbers indicate percentage of COVID-19 positives and negatives reporting taste
231 or smell loss (blue and green respectively), both taste and smell loss (turquoise) or neither
232 (seashell). B. The prevalence of the four taste modalities in COVID-19 positive and
233 negative patients. COVID-19 positives are represented in purple and COVID-19
234 negatives are represented in orange

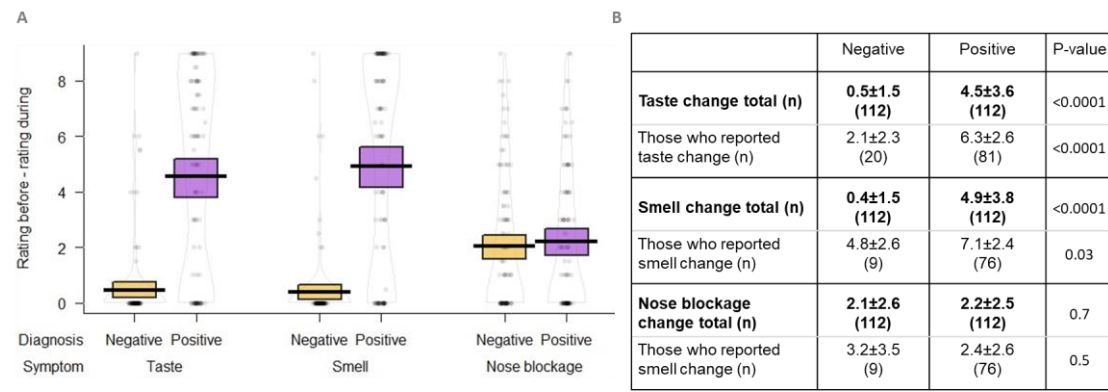

235

236 Approximately 60% of the positive patients reported impairment of at least one of the
237 four taste modalities (sweet, salty, sour, and bitter) compared to only ~6% among the
238 negative patients (Figure 2B). In COVID-19 positive patients with taste impairment, all
239 four taste modalities were usually impaired. In 31% of the positive patients and in 90%
240 of the negative ones, no taste modality was impaired.

241

242 **Chemosensory changes rating and details**

243 In addition to the binary questions, the participants were asked to rate their smell and
244 taste senses before and during their illness on a 1-10 scale.

245

246 **Figure 3. Degree of taste, smell and nose blockage in COVID-19 positives and negatives. A.**

247 Histogram showing the change in rating during the illness minus rating before the illness for

248 taste, smell, and nose blockage. No change is coded 0 and the highest change is 9. COVID-19

249 positives are represented in purple and COVID-19 negatives are represented in orange. **B.**

250 Table of mean ± SD for COVID-19 positives and negatives in general and for those reporting

251 changes of taste or smell. Scores for taste, smell, and nose blockage were evaluated on a 1-10

252 scale. P values for the difference in the magnitude of change between COVID-19 positives and

253 negatives was calculated using a two-sided t-test.

254

255 As is seen in Figure 3, the change in smell and taste ability during disease, compared

256 to a self-reported individual baseline before the disease, differs greatly between

257 positive and negative patients. Both taste and smell changes were significantly greater

258 for COVID-19 positive patients compared to COVID-19 negative patients (4.5±3.6 and

259 4.9±3.8 vs. 0.5±1.5 and 0.4±1.5, mean ± SD, p<0.0001 and p<0.0001, respectively).

260 When considering only patients who reported taste or smell changes (answered “yes”

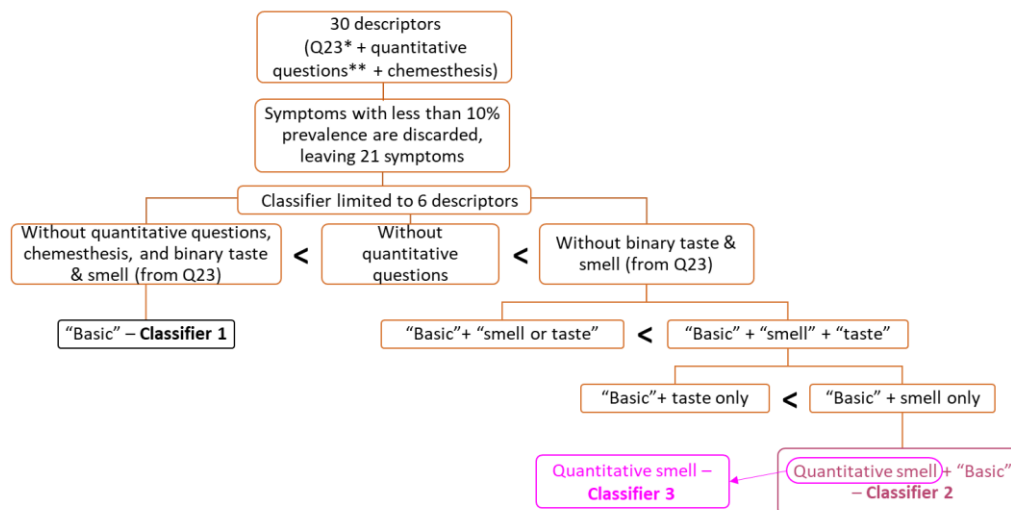

261 to the respective binary questions), the averages in positive patients were 6.3±2.6 for

262 taste and 7.1±2.4 for smell, compared to negative patients with 2.1±2.3 for taste and

263 4.8±2.6 for smell (among patients with any change in taste p<0.0001, in smell

264 p<0.0001).

265 We next set out to check which combination of symptoms will be most useful for
 266 differentiating between COVID-19 positive and COVID-19 negative diagnosis. To that
 267 end, several classifiers were trained based on 66% of the sample and evaluated on
 268 34% that was kept as a holdout set. The process of selection of descriptors is outlined
 269 in Figure 4. Relevant symptoms (n=30) were included as possible descriptors for the
 270 classifiers, and the elastic-net penalization was increased until no more than six
 271 symptoms were included in the model (number limited for practicality). The effect of
 272 excluding or including a particular symptom was evaluated in order to understand the
 273 importance of separating taste from smell and using binary vs. quantitative measures
 274 for each (Figure 4).

*includes all symptoms in question 23 excluding "no symptoms", coding "other" to "fatigue" and "dizziness", and grouping eye symptoms
 **includes taste, smell and nose blockage.

275

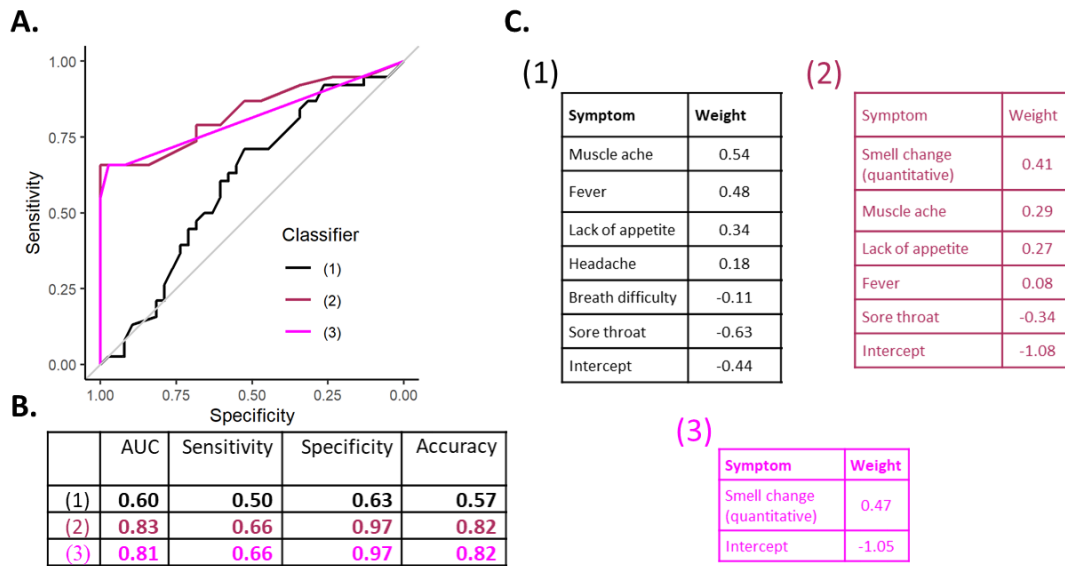

276 **Figure 4. Descriptors selection process for classifiers.** The flow chart depicts total symptoms
 277 selected for the classifiers. Upon limiting the number of descriptors for the classifiers and
 278 excluding chemosensory symptoms as described, Classifier 1 was created. Different
 279 combinations of symptoms established better classifiers than Classifier 1, those using
 280 quantitative questions exhibiting better performance than those using binary ones. The

281 classifier using "smell" and "taste" as separate descriptors, rather than "smell or taste" as a
282 single joint descriptor showed better performance. The "Basic" + smell only descriptor
283 outperformed the "Basic" + taste only descriptor, resulting in Classifier 2. Finally, the smell
284 only descriptor was tested alone without all other "Basic" symptoms, resulting in Classifier 3.

285

286 The results of the evaluation on the holdout set are summarized in Supplementary
287 Table 1, and classifiers 1-3 can be seen in Figure 5. Classifiers that did not use
288 chemosensory symptoms had poor performance (AUC 0.60, black curve, classifier 1,
289 and additional classifiers (Table S1). Adding the quantitative smell-change symptom
290 (maroon curve, Classifier 1) is sufficient to outperform all other classifiers (AUC 0.83).
291 Remarkably, using quantitative smell-change as a sole symptom (magenta curve,
292 Classifier 3) resulted in a classifier that was nearly equally effective as Classifier 2 (AUC
293 0.81).

294 Adding taste change to Classifier 2 did not improve its performance, as it resulted in
295 AUC of 0.82 (Classifier 7, Table S1). Furthermore, taste change as a sole descriptor
296 resulted in AUC of 0.75 (Classifier 15, Table S1) and as an added descriptor to other
297 "Basic" symptoms, it resulted in AUC of 0.76 (Classifier 13, Table S1). Thus, while there
298 is a high correlation (0.82) between quantitative changes in smell and quantitative
299 changes in taste, in our sample the smell change descriptor outperforms the taste
300 descriptor. Using the quantitative smell and taste descriptors resulted in higher AUC's
301 than binary (yes/no) descriptors of these changes. For example, a binary smell
302 descriptor used as a sole descriptor resulted in AUC of 0.78 (Classifier 16, Table S1), as
303 compared to AUC of 0.81 using quantitative smell descriptor.

304

305

306 **Figure 5. A.** ROC curves for the classifiers considered. **B.** Statistical parameters for the ROC
 307 curves. For the quantitative descriptors, the coefficients correspond to a descriptor scaled to
 308 the 0-1 range. **C.** Descriptors, their coefficients and intercept (fitted parameter) used in
 309 Classifiers 1, 2 and 3.

310

311 Scores according to the classifiers can be readily transformed into the probability for
 312 COVID-19, under additional factor: the known rate of positive tests. The rate of
 313 positive tests out of total PCR tests at the time of participants recruitment was
 314 calculated to be 8% based on data from Israeli Ministry of Health. By incorporating this
 315 factor (as described in the Methods), we were able to reach PPV of 0.68 and NPV of
 316 0.97 for both classifiers. A probability calculator based on Classifiers 2, 3 and 13 (from
 317 Supplementary) is available in GITHUB
 318 (https://github.com/KimAsseo/Hadassah_COVID-19) and may be used for practical
 319 purposes in clinical life.

320

321 **DISCUSSION**

322 We have established the prevalence and degree of decrease in taste and smell in
323 patients who were eligible to receive PCR swab tests during the COVID-19 pandemic
324 and found significant differences in PCR-positive and PCR-negative patients.

325 The change in smell ability is not related to nasal obstruction, as nose blockage was
326 low, in accord with previous studies[7, 23]. Taste and chemesthesis changes strongly
327 correlate with smell change (also shown and discussed by Parma[7]). Taste changes
328 are more common in negatives, and chemesthesis are less common in positives,
329 leading to odds ratios for these chemosensory modalities that are high, but lower than
330 for olfaction. Accordingly, taste and chemesthesis were not captured by the
331 classification analysis as characteristics contributing to improvement of the classifier.

332 All taste modalities in COVID-19 patients were impacted together (or not at all). This
333 is of interest for understanding the pathophysiology of the disease: a recent study
334 suggests CoV-2 infection of non-neuronal cell types expressing ACE2 and TMPRSS2 as
335 the mechanism underlying COVID-19 related anosmia[24], but the reason for COVID-
336 19 ageusia is less clear [19, 25]. Our results support the idea of impairment of
337 supporting cells or tissues, rather than of taste receptors cells Type 2, which express
338 bitter, sweet and umami taste receptors or Type 3 which express sour sensing
339 channels [26]. However, our observation that individual taste modalities and general
340 taste ability are greatly impaired in COVID-19 patients did not warrant addition of
341 taste questions for patients screening, as these did not contribute to the classifier
342 performance. Nevertheless, patients with prior conditions of impaired olfaction
343 (estimated 5% of population[27]) require a suited classifier.

344 We thus present three versions of classifiers: the first one is based on four yes/no
345 questions (muscle ache, lack of appetite, fever, sore throat) and the quantitative smell
346 change calculated from self-rating of smell perception before and during the current
347 illness. The second version uses only the quantitative smell change and has a similar
348 AUC. The third one (suited for participants with pre-existing olfactory impairment) is
349 based on five yes/no questions (muscle ache, lack of appetite, fever, sore throat,
350 breath difficulty) and quantitative taste change. The probabilities for COVID-19 based
351 on these calculators are available via Github.

352 Our study confirms previous reports [21, 28] showing an association between changes
353 in smell and taste with the positive status of COVID-19. Our best-performing classifier
354 (Classifier 2, AUC 0.83) used symptoms found to be predictive also by Menni *et al.*[14].
355 Specifically, these authors reported chemosensory loss and loss of appetite as
356 positively contributing. However, their chemosensory descriptor is "loss of smell and
357 taste", while ours involves quantitative smell change.

358 Our study was performed in parallel to Gerkin *et al.*[18], and similarly included both
359 binary and quantitative questions regarding taste and smell as two separate
360 indicators. Our results for positive patients are in overall agreement with Parma *et al.*
361 *et al.*[7] and Gerkin *et al.*[18]. This is striking in view of the different methods employed
362 for recruitment (targeting smell and change impairment worldwide vs PCR-positive
363 COVID-19 patients in Israel), data collection (online survey vs telephone interviews),
364 and quantitative scales (100-point visual analogue scales (VAS) vs. 1-10 scale in this
365 0/82study). In essence, both Gerkin *et al.* and the current study suggest that
366 quantitative smell change is the best predictor of COVID-19 in single and in cumulative
367 feature models and is better than binary feature. The superior performance of the

368 classifier (AUC of 0.83 vs. 0.72 in [18]) is probably due to a more realistic
369 representation of our sample, in which chemosensory losses were not over-
370 represented.

371 With the increasing public awareness to smell impairment as COVID-19 characteristic
372 symptoms, individuals presenting smell and taste change are now more likely to be
373 suspected of having COVID-19. By considering other symptoms and the severity of
374 chemosensory change, our calculators provide a free, fast and easy to use tool that
375 can provide immediate answers for patients awaiting their PCR-swab test results and
376 potentially decrease anxiety of negative patients who experienced smell and taste
377 impairments.

378

379 **Study limitations**

380 The method of patient recruitment is one of the limitations of this study: social media-
381 based recruitment may limit participants' representation as it targets mostly younger
382 patients, with internet access and social media accounts. Word of mouth recruitment
383 was used as well and contributes as well to creating a sample that is not necessarily
384 representative of the general population. Male and female patients were not fully
385 matched across positives (64% males) and negatives (48% males), in accord with
386 higher % of males (56%) among COVID-19 patients in Israel.

387 Importantly, symptoms-based classifiers cannot capture asymptomatic COVID-19
388 patients. Therefore, low probability established with our classifiers should not be
389 considered as a predictor of negative COVID-19 status. In other words, our classifiers
390 are not SNOOUT ('Sensitive test when Negative rules OUT the disease') but can
391 definitely be referred to as 'Specific test when Positive rules IN the disease' (SPIN).

392 While chemosensory loss is a dominant feature of symptomatic COVID-19 patients,
393 about 30% of them do not report such loss. Our sample was not large enough to
394 include many positive patients in this subgroup, and further studies are needed to
395 capture distinctive characteristics of COVID-19 patients with intact smell and taste.

396 Additionally, our sample was composed of light to moderately ill patients, thus the
397 classifiers reported are not necessarily applicable to patients with severe forms of
398 COVID-19. It should also be kept in mind that our data is specific to Israeli patients and
399 reflect to some degree the criteria for PCR tests eligibility during the recruitment
400 (fever and dry cough were sufficient for PCR test but change of smell and/or taste
401 alone was not).

402 Another possible limitation of this study is the self-reporting, rather than objective
403 testing method for data collection used. Clearly, the infectious nature of the disease
404 cause data collection to be mostly based on self-reports[29], but classifiers based on
405 brief objective examination of taste and smell symptoms may provide additional
406 insights.

407 Lastly, RT-PCR is a commonly used diagnostic test for COVID-19 and for that reason it
408 was used in the present study as a distinguishing criterion. Nevertheless, even this test
409 may report false diagnosis (26%-37%)[30, 31]. Considering the inaccuracy of PCR tests,
410 high scores from our classifiers may help to reinforce true positive results and possibly
411 capture PCR false negative patients.

412

413 **CONCLUSIONS**

414 The resurging pandemic puts the clinic and public health authorities in a scenario not
415 usual for modern medicine – namely, the limited resources require or may require in

416 the future, prioritization of testing and treatment. The fact that our sample contained
417 PCR-positive and PCR-negative ambulatory patients, all suspected to have COVID-19
418 prior to PCR testing, enabled the development of symptoms-based classifiers.

419 Our results suggest that ranking of the ability to smell before and during the illness, is
420 an excellent practical approach to identify COVID-19 positive patients offering
421 reasonably high predictive capability (Specificity 97%, Accuracy 82%). Additional
422 classifier is available for patients with prior olfactory impairments (Supplementary
423 Material Table S2).

424 Based on the classifiers developed in this work, we propose a simple calculator that
425 can be used to prioritize testing (available at
426 [https://github.com/KimAsseo/Hadassah COVID-19](https://github.com/KimAsseo/Hadassah_COVID-19)). Additionally, high-performance
427 classifier may potentially capture false negative PCR tests results of high scored
428 individuals. Detection and isolation of potential COVID-19 patients is of crucial
429 importance for pandemic containment but remains a persistent challenge worldwide
430 due to lacking accessibility to tests. While further research is required, the current
431 study provides a practical tool for assessing potential COVID-19 patients.

432

433 **LIST OF ABBREVIATIONS**

434 CDC - Centers for Disease Control and Prevention

435 SARS-CoV-2 - Severe Acute Respiratory Syndrome Coronavirus 2

436 SARS - Severe Acute Respiratory Syndrome

437 VAS - Visual Analog Scale

438 SD - Standard Deviation

439 GCCR - Global Consortium for Chemosensory Research

440 AUC - Area Under the Curve

441 PPV – Positive Predictive Value

442 NPV – Negative Predictive Value

443 RT - Real Time

444 PCR - Polymerase Chain Reaction

445 SNOUT - Sensitive test when Negative rules OUT the disease

446 SPIN - Specific test when Positive rules IN the disease

447 ROC curve - Receiver Operating Characteristic curve

448

449 **CONFLICT OF INTEREST**

450 The authors declare that they have no competing interests.

451

452 **AUTHORSHIP CONTRIBUTION**

453 NK and MYN initiated the research, NK and MN recruited patients, NK, MYN, YB

454 and MM and designed the research, SI, MM, RNP and MYN supervised the research,

455 HK carried out the interviews, HK and MYN drafted the manuscript, KA and YB

456 preformed the statistical analysis and created figures and tables. All authors contributed

457 to writing and approved the final manuscript.

458

459 **ACKNOWLEDGEMENTS**

460 MYN is supported by Masha Niv is supported by Israel Science Foundation grant

461 #1129/19. HK is a recipient of the Uri Zehavi Scholarship.

462

463 **Ethics approval and consent to participate**

464 The study was conducted in accordance with Helsinki committee and the required ethics

465 approval was granted (reference number HMO-0236-20).

466

467 **Consent for publication**

468 Written informed consents for publication of patients' clinical details were obtained
469 from the patients.
