8	
9	Highlights:
10	1.We predicted future COVID-19 occurrences in mainland of China based on ARIMA model.
11	2. We validated the model based on the previous outbreak data with actual data for June, 2020.
12	3. The measures taken by the government have contained spread of the epidemic
13	4. The combination of multiple models may improve the robustness of the model
14	
15	Abstract: The ongoing pandemic of COVID-19 has aroused widespread concern around the
16	world and poses a severe threat to public health worldwide. In this paper, the autoregressive
17	integrated moving average (ARIMA) model was used to predict the epidemic trend of COVID-19
18	in mainland of China. We collected the cumulative cases, cumulative deaths, and cumulative
19	recovery in mainland of China from January 20 to June 30, 2020, and divided the data into
20	experimental group and test group. The ARIMA model was fitted with the experimental group

29

## 30 1. Introduction

31	COVID-19 has spread worldwide and has caused tens of thousands of human deaths. At the
32	same time[1], it has a huge impact on the world's medical, public health, economic, and other
33	aspects [2]. In order to effectively suppress the spread of COVID-19, the Chinese government has
34	successively announced the launch of a first-level response mechanism for major public health
35	emergencies and implemented strict prevention and control measures[3]. By the end of June 2020,
36	mainland of China had 85000 confirmed COVID-19 cases and 4648 deaths. Although the situation
37	of prevention and control is getting better, the global situation is still not optimistic.
38	ARIMA model considers the law that the historical data of the research object itself changes
39	with time, and uses this to predict future values, that is, to replace various influence factors with
40	time. At present, the advantage of ARIMA model in predicting infectious diseases has been
41	confirmed in many studies[4-5].
42	This study is based on the autoregressive integrated moving average model to predict the
43	cumulative cases, cumulative deaths, and cumulative recovery of COVID-19 in mainland of China,
44	and select the most appropriate model to simulate the epidemic pattern by simulating multiple
45	models. A preliminary explanation is given to evaluate the effects of the epidemic prevention and
46	control measures at this stage.
47	
48	2. Data and Methods

49 2.1 Data Sources

50 The COVID-19 case data comes from the National and local health and construction

- 51 commission daily information release (https://ncov.dxy.cn/). We collected the cumulative cases,
- 52 deaths, recovery in mainland of China from January 20, 2020 to June 30, 2020.
- 53
- 54 2.2 Methods

55	ARMA model is a stationary time series model, but COVID-19 daily cases, deaths and
56	recovery changes with volatility, uncertainty, is a non-stationary random process, so this article
57	introduces the difference operator I (The original non-stationary time series can be improved into
58	a stationary time series after d-order difference), establish the COVID-19 cumulative cases, deaths,
59	and recovery trend prediction ARIMA model. In recent years, the ARIMA model has become one
60	of the most commonly used methods in the prediction of many epidemics. This method is
61	particularly suitable for short-term prediction of infectious diseases, and its prediction accuracy
62	has been widely recognized, at the same time, it can also provide effective help for disease
63	prevention and policy-making[6].

ARIMA model is composed of autoregressive model (AR model (P)), moving average model(MA model (q)) and difference operator I (d), where p, d and q are autoregressive order, difference order and moving average order of time series[7]. The expression of the p-order AR model is as follows:

68 
$$Y_t = C_1 + \alpha_1 Y_{t-1} + \alpha_2 Y_{t-2} + \dots + \alpha_p Y_{t-p} + e_t \quad (1)$$

Where αi (i=1,2,...,p) is the AR model coefficient, et is the random interference term, and
C<sub>1</sub> is the constant.

71 The mathematical expression of the q order MA model is:

72 
$$Y_t = G(B)e_t + c2$$
 (2)

73 
$$G(B) = (1-\beta_1 B - \beta_2 B^2 - \dots - \beta_q B^q) \quad (3)$$

74 Where  $\beta_j$  (j=1,2,...,q) is the MA model coefficient,  $e_t$  is the random interference term, and  $c_2$ 

75 is the constant.

- 76 Combining the time series after the difference of order d, the final expression of the ARIMA
- 77 model is:

78 F(x) = 
$$c + \alpha_1 X_{t-1} + \alpha_2 X_{t-2} + ... + \alpha_p X_{t-p} + \beta_1 e_{t-1} + ... + \beta_q e_{t-q}$$
 (4)

79 Where  $\alpha$  represents the coefficient of AR,  $\beta$  represents the coefficient of MA, and c is the

80 constant term.

81 ARMA model construction (Fig.1 The flowchart of ARIMA modelFig.1) :

82 (1) Data difference: the collected COVID-19 data are divided for several times to make it
83 stable, and then the autocorrelation and partial autocorrelation tests are performed on the
84 differential data.

(2) The choice of modeling parameters: according to an information criterion (AIC) and
Bayesian information criterions (BIC), combing with the autocorrelation function (ACF) and
partial autocorrelation function (PACF) of the residual sequence to determine the order of the
model, and finally select the model with the highest fitting degree[8].

- 89 AIC=-2ln(L)+2m (5)
- 90 BIC=-2ln (L) +mln (n) (6)

91 Where: L is the maximum likelihood function of the model, m is the number of estimated92 parameters, and n is the sample size.

93 (3) Verify the reliability of the model: we use the model to predict the cumulative cases,94 deaths, recovery in Chinese provinces (excluding Hong Kong, Macao, and Taiwan) from June

- 95 1-30, 2020, calculate the relative error from the actual cases, and verify the model predictive
- 96 effect.
- 97

98

99

Fig.1 The flowchart of ARIMA model

# 100 **3. Results**

We build a model based on the cumulative cases, deaths, and recovery data in mainland of
China from January 20 to May 30, 2020. Here we take Hubei Province as an example to describe
the recognition process of the model.
First, we build the original time series figure (Fig.2), from the figure, we can see that the
initial outbreak of COVID-19 increased exponentially. The Chinese government took timely
measures to control the epidemic. It can be seen from Fig.2 that the original data time series are
not stationary, so we need to carry out first-order differential processing on the original data. The

- 108 processed time series is shown in Fig.3. Since the time series in Fig.3 is still unstable, we need to

- 109 make two difference, d = 2, as shown in Fig.4. It can be seen from the figure that the data floats up
- and down in "0", which can judge that the data is stable after the second-order difference, so d = 2

#### 111 is determined.

112

Fig.2 The cumulative cases, deaths, recovery original time series figure

Fig.3 First-order difference processing time series figure (d=1)

116

118

Fig.4 Second-order difference processing time series figure (d=2)

119

After the d value is determined to be 2 by differential processing, we need to select different combinations of p and q values to test the goodness of fit, and use the models with relatively small AIC and BIC values as the best model, and then verify the model.

In the end, we obtained the models for predicting the cumulative cases, deaths, and recovery in Hubei Province as ARIMA(0,2,1), ARIMA(1,2,1), ARIMA(1,2,4). The residual of the model is tested by white noise sequence. As shown in Fig.5, the autocorrelation function and partial autocorrelation function of the residual sequence are basically within 95% confidence interval, indicating that there is no autocorrelation in the residual sequence. Then the model through the white noise test, the model can be used to predict the cumulative cases, deaths, and recovery in Hubei Province.

132

Model test and error analysis : We divided the data into experimental group (January 20 May 31, 2020) and test group (June 1 - June 30, 2020), First of all, we bring the data of the
experimental group into the ARIMA model of the cumulative cases, deaths, recovery in each
province, and calculate the average relative error between the actual number and the fitted value.
The results are shown in Table 1.
Table 1

#### 145 Note: \* means that the cumulative death is 0, which cannot be calculated.

146

147 It can be seen from Table 1 that the average relative error of the cumulative cases in each 148 province is between -2.92% and 3.82% (except for Guangdong Province); the average relative 149 error of the cumulative cases in Guangdong Province is 19.64%. By analyzing the data of 150 Guangdong Province, we found that on January 23, 2020, the actual cumulative cases were 26, 151 and the fitting value was 1. This is mainly since at the early stage of the epidemic, the 152 transmission route of COVID-19 was not known, and the government did not take effective 153 measures, so the number of cases increased exponentially, which led to a large error at that time. 154 The average relative errors of cumulative deaths and recovery in various provinces are between

- 155 0-2.46% and -8.57%-4.13%, the errors are small and the fit is good, so the model is suitable. We
- 156 further analyzed the average relative error between the actual cases and the predicted values in
- each province of the test group (June 1 June 30, 2020). The results are shown in Table 2.
- 158

Qinghai	0.00%	*	0.00%
Yunnan	0.00%	0.00%	0.44%

Note: \* means that the cumulative death is 0, which cannot be predicted.

163

164 It can be seen from Table 2 that the average relative errors of actual cumulative cases, deaths,

recovery and predicted values in each province are between -22.32%-22.66%, -9.52%-0.08%,

-8.84%-1.16%. The results of comprehensive experimental group and test group show that the
error between fitting and prediction is small, the fitting effect is good, the model supports and is
suitable for epidemic situation prediction.

169 COVID-19 trend in mainland of China: According to each provincial model, we get the 170 overall trend of COVID-19 in mainland of China, as shown in Fig.6. The trend of the fitting line 171 between the predicted value and the actual value of the cumulative cases, deaths and recovery was 172 consistent (6a, 6b, 6c). At the beginning of the epidemic, the cases showed an exponential upward 173 trend. At the end of January, the Chinese government took measures to seal the city, isolate it from 174 the source of infection, and reduce the possibility of infection, the epidemic was controlled in 175 mainland of China. The epidemic situation in Hubei, Guangdong, Zhejiang, Henan and other 176 places in mainland of China is relatively serious (6a). Residents in this area still need to do 177 epidemic prevention and control work to prevent the possibility of a second rebound of the 178 epidemic situation.

179 With the increase of confirmed cases, the number of deaths initially gradually increased. It 180 can be seen from 6b that the number of deaths in mid-April showed a linear upward trend. The 181 reason for this data surge is that the preliminary data statistics are incomplete, the statistical 182 standards are inconsistent and there are varying degrees of delay in the statistical process [9]. The 183 state has proposed efforts to reduce deaths, requiring provinces to increase the number of 184 ventilators to ensure adequate medical facilities. The number of deaths in mainland of China has 185 remained stable around May. In this fight against the epidemic, many volunteers have appeared in 186 many places, and medical personnel throughout the country have conducted targeted research on 187 the epidemic, and their experience and level have been improved, resulting in the continuous

189

196

# 197 **4.Discussion**

198	Data from January to June 2020 shows that the epidemic in mainland of China has peaked at
199	the end of February and has been steadily declining since then. This is mainly due to the closed
200	management measures taken by the Chinese government in the face of the COVID-19 pandemic
201	to stop population-intensive Place, and achieved good results. By the end of March 2020, all
202	regions had lifted the closure measures and adjusted the primary response to major public health
203	emergencies to secondary, and the cases in the epidemic have not changed significantly since then.
204	This may be related to climate factors such as continuous temperature increase in various places.
205	The studies have shown that changes in temperature and humidity may be important factors
206	affecting the spread of COVID-19[10].
207	In recent years, ARIMA model, neural network and so on are more active in the field of
208	epidemic prediction because they can relatively accurately explore the occurrence and
209	development of epidemics[11-15].
210	The reason why ARIMA model can be widely favored in the field of epidemiological
211	prediction is that it not only absorbs the advantages of traditional regression analysis but also takes
212	advantage of the moving average, and can affect many factors affecting the development of the
213	epidemic (such as temperature, humidity, aerosol, population migration, etc.) integrated into time
214	variables for quantitative expression, is a method with strong practicability and high prediction
215	accuracy. However, ARIMA model also has certain limitations. It is a mathematical model built
216	on past historical data. Therefore, ARIMA model is only suitable for short-term forecasting. If the
217	forecasting time is too long, it will increase the forecasting error and affect the forecasting
218	accuracy[16-18].

219	At present, COVID-19 has become a global epidemic, and the epidemic situation is still
220	accelerating and has not yet reached its peak. The prevention and control of the epidemic situation
221	must not be delayed. Based on the COVID-19 data of mainland of China, we found that the model
222	has a high degree of fitting, which can predict the development trend of the epidemic situation in
223	the future. However, in practice, other factors[19-22] will also affect the development trend of the
224	epidemic situation, causing predictions to deviate, this needs further study. In practical
225	applications, we can make the model have better prediction effect and accuracy by combining
226	with multiple models.
227	5.Conclusion
228	We used the epidemic data of Chinese provinces from January 20 to June 31, 2020, in which

242	Ackno	wledgements: This work was financially supported by spatial data analysis and						
243	geosci	entific calculation are used to study urban vulnerability based on microgeographic						
244	units(g	rant numbers: 41461035). Thanks to the National and local health and construction						
245	commi	ssion for providing data on the daily cumulative cases, deaths and recovery.						
246								
247	Declar	ration of Interest Statement: No conflict of interest exits in the submission of this						
248	manus	cript, and manuscript is approved by all authors for publication. I would like to declare on						
249	behalf of my co-authors that the work described was original research that has not been published							
250	previously, and not under consideration for publication elsewhere, in whole or in part. All the							
251	authors listed have approved the manuscript that is enclosed.
