6
7 **Abstract** This study is a retrospective chart review of 200 clients who participated in a non-
8 verbal restorative Cognitive Remediation Training (*r*CRT) program. The program was applied to
9 effect proper neural functional remodeling needed to support resilient, flexible and adaptable
10 behaviors after encountering a mild to medium closed head traumatic brain injury (mTBI). The
11 *r*CRT training program focused on improving functional performance in executive cognitive
12 control networks as defined by fMRI studies. All *r*CRT training activities were delivered in a
13 semi-game-like manner, incorporating a Brain Computer Interface (BCI) that provided *in-the-*
14 *moment* neural network performance integrity metrics (nPIMs) used to adjust the level of play
15 required to properly engage long-term potentiation (LTP) and long term depreciation (LTD)
16 network learning rules.

17
18 This study reports on t-test and Reliable Change Index (RCI) changes found within cognitive
19 abilities' performance metrics derived from the Woodcock Johnson Cognitive Abilities III Test.
20 We compared pre and post scores from seven cognitive abilities considered dependent on
21 executive cognitive control networks against seven non-executive control abilities. We observed
22 significant improvements (p values 10^{-4} to 10^{-22}) with large Cohen's d effect sizes (0.78-1.20)
23 across thirteen cognitive ability domains with a medium effect size (.49) on the remaining. The
24 mean percent change for pooled trained domain was double that observed for pooled untrained

25 domain, at 17.2% versus 8.3%, respectively. To further adjust for practice effects, practice effect
26 RCI values were computed and further supported the effectiveness of the rCRT training (RCI-
27 trained 1.4 - 4.8; untrained RCI 0.08-0.75).

28

29 **1.0 Introduction** Mild to acute TBIs can lead to lingering changes in an individual's neurologic
30 performance, resulting in debilitating and far-reaching consequences in adaptive cognitive
31 functioning. Annually, as many as 5.3 million people in the U.S. are thought to face challenges
32 due to TBI-related disabilities [1]. However, the actual number of chronic TBI (> 6 months post-
33 injury time) may be greater. This is due to limited testing sensitivity of typical testing methods
34 for TBI based on conventional neuropsychological measures and/or conventional clinical
35 imaging methods (e.g., CT, MRI scanning) coupled with a lack of public awareness with regard
36 to mTBI symptoms [2,3].

37

38 Concussions represent 80% of the traumatic brain injuries (TBI) occurring each year in the
39 United States [4-8]. Concussions are often related to sports injuries, but the bulk of concussions
40 are due to motor vehicle accidents, falls, and situations involving sudden acceleration and/or
41 deceleration of the head [4-8]. TBIs have been long considered an injury with little recourse, but
42 recent awareness of the long-term effects of concussion has led to a renewed emphasis on
43 treating TBI and concussions. If not treated properly, an instantaneous insult can be the
44 beginning of a chronic disease process rather than just an isolated event. This disease process
45 occurs across all levels of initial injury severity, from mild to severe [5-8]. For example, TBIs
46 are implicated as a risk factor for cognitive impairments, reduced social functioning, psychiatric
47 disorders, and chronic traumatic encephalopathy [9-13].

48 TBI Cognitive Deficits Cognitive deficits are some of the most common and undermining after-
49 effects of a TBI. Such deficits may drastically interfere with an individual's adaptive resiliency
50 or ability to adapt to social and vocational collaborations, especially under mild stress conditions
51 [14,15]. After a TBI, many major cognitive disruptions are triggered due to impaired gray matter
52 or white-matter connections, often incurred by diffuse axonal injuries (DAI) [16]. DAIs foster
53 multi-focal disturbances to axons that provide the structural basis of spatially distributed brain
54 networks [17-21]. Consequently, a DAI often leads to interruptions in brain network
55 connectivities, where these interruptions can be reflected in behavioral performance [17-21]. In
56 the context of rehabilitation, both active brain network performance and resting state functional
57 connectivity (rsFC) metrics (measured using EEG or fMRI methods) are promising tools to
58 measure neuroplasticity changes within an injured brain after injury [22-37]. These metrics can
59 also provide evidence for experience-induced neuroplasticity changes acquired using rCRT
60 methods [17-37].

61 Brain network performance deficits and/or DAI dysfunctions are often rooted in neural networks
62 that sub-serve communications between larger networks. These larger networks support
63 foundational neurobehaviors such as attention, memory, and executive functioning. White matter
64 (WM) substructures of these networks and the efficiency of neural network hub connections
65 (nodal connections within neural networks) demonstrate significant relationships with behavioral
66 performance scores on intelligence testing [38-44]. Higher IQ scores correlate with higher
67 nodal efficiency in the right anterior insula (AI) and dorsal anterior cingulate cortex (dACC),
68 two hub regions within the salience network, with both regions shown to be vulnerable to
69 mTBIs [38-44] and implicated in various mental health conditions [45-51]. Likewise, higher
70 scores are linked to *lower nodal efficiency* in the left temporo-parietal junction area (TPJ).

71 Disruptions or lack of resiliency within these foundational neurobehaviors can impact various
72 cognitive functions and emotional regulation abilities [17-21]. Spontaneous neural network
73 reorganization resulting in a partial motor and cognitive recovery is commonly thought to occur
74 in the first 3 to 6 months postinjury [52]. However, recent studies indicate that many deficits
75 linger and are present years later [53-56]. Equally important, EEG performance studies indicate
76 that the brain remodels or reorganizes to achieve a more normal behavioral performance; the
77 remodeling may or may not have long term negative impact, depending on how the remodeling
78 occurs [22-37]. Cognitive rehabilitation studies suggest that significant proper remodeling can be
79 achieved by using cognitive rehabilitation exercises to reduce the cognitive and behavioral
80 consequences of a mTBI [54-56]. Such exercises are the subject of this paper.

81 *Restorative Cognitive Rehabilitation Training (rCRT)* Cognitive rehabilitation training (CRT)
82 methods are an organized, functionally oriented set of therapeutic activities based on a neural
83 assessment. CRT treatments target the patient's cognitive and behavioral deficits [54-56].
84 Fundamental to the CRT process is the brain's ability to be remodeled through behavioral
85 experience via neural plasticity changes, or the brain's ability to reorganize and relearn, by
86 redirecting maladaptive plasticity towards a more functional neural growth state [14-22]. CRT
87 methods divide into restorative interventions (*rCRT*) and compensatory methods (*cCRT*). *rCRT*
88 principally intervenes in cognitive disturbances or disrupted neural performance caused by brain
89 impairment or disrupted function to promote brain performance normalization. *cCRT* seeks to
90 establish alternative patterns of cognitive activity or create new patterns of movement through
91 external support devices (e.g., adaptive aids, prosthesis) to improve the patient's quality of life
92 [54-56].

93 *rCRT Remediation Change Markers – Reliable Change Index, Cognitive Abilities and Resilience*

94 Intelligence (cognitive ability) characterizes the ability to solve problems unrelated to previously
95 learned knowledge, an essential element in resilient behavioural expressions [57]. These abilities
96 underwrite encoding and use of new information with its efficient manipulation, representing a
97 critical component of human cognition [39-45;58,59]. Equally, these abilities strongly predict
98 educational and professional success [59], making the neural networks that support these
99 operations obvious training targets. Cognitive neuroscience research supports this choice. For
100 example, Santarnecchi et al. (2015) documented the association between individual intelligence
101 quotients (IQ) and brain resilience by simulating targeted (specific network nodes) and random
102 attacks using resting-state fMRI and graph analysis methods (n= 102 healthy individuals). The
103 authors found enhanced brain resilience to targeted attacks (TA) were correlated with higher IQs
104 in networks belonging to language and memory processing regions, whereas regions related to
105 emotional processing were mostly supported in lower IQ individuals. These results suggest that
106 both pre and post changes in IQ scores may be useful training predictors for recovery.

107 *Retrospective Chart Review Study* This study reviewed 200 clients who participated in a *rCRT*-
108 based program to promote proper remodeling of neural function after a TBI. The approach
109 employed the NeuroCoach® Training System, an automated *rCRT* activity/brain-computer
110 interface system that develops targeted neural circuit responses towards resilient, flexible and
111 adaptable behaviors. The approach applies algorithmically leveled brain training activities to
112 support psychological resilience.

113 **2.0 Methods** The study design employed a retrospective chart review to formulate results
114 derived from participants who had previously participated in a BCI-augmented CRT program as

115 a post-conventional treatment follow-on component of their mTBI recovery program. Our study
116 protocol, 20-NEUR-101, was determined by an independent Institutional Review Board to be
117 Exempt according to FDA 21 CFR 56.104 and 45CFR46.104(b)(4). Our use of data was
118 retrospective, and data were processed for analysis in a manner which precluded identification of
119 individuals. Informed consent was obtained in writing from all participants. To explore treatment
120 effects, this study used a battery of Woodcock Johnson III (WJIIIICA) assessments. Participant
121 testing record results obtained from WJIIIICA testing were structured with dependent pre- and
122 post-test sampling using the same evaluation methods in both pre and post testing. Each
123 participant received an individualized program designed to address neurobehavioral imbalances
124 in their executive function and emotional regulation. Targeted treatment variables focused on
125 remediating deficiencies observed in participants' cognitive control, memory, attention, and
126 executive function. Neurobehavioral imbalances were addressed using an advanced form of a
127 CRT employing a BCI method to influence CRT training activities based on the cognitive
128 information processing strength of each imbalance in real time [60-62]. Collection of data and
129 subsequent analyses of those data were conducted by different persons, which helped both to
130 ensure confidentiality and preclude bias from analysis.

131 Participants The TBI treatment group was composed of 200 participant records (n=200: 110
132 males and 90 females). The following training inclusion criteria were used: (1) mTBI derived
133 from Sports, MVA, work related, and or recreational activity related; (2)>180 days post injury;
134 (3) no histories of schizophrenia, bipolar disorder, eating or obsessive-compulsive disorder. Each
135 group received the same pretest and posttest. Adult participants (aged 18 or older) previously
136 classified with a closed head injury TBI were recruited from outpatient programs and private
137 practices. The mean age of participants was 31.3 years. All records were de-identified using

138 standard safe-harbor methods to protect the anonymity of individual health information.

139 Participants volunteered for pre- and post-testing with treatment based on a deliberate self-
140 selection convenient sample method. Volunteering did not affect the type of treatment received;
141 specifically, those who did not volunteer or qualify for the study received the same BCI
142 Amplified CRT Training as those who did. The treatment group was tested before treatment and
143 upon treatment completion. All participants paid identical fees for treatment.

144 Pre- and Post-Test Measures This study employed neurophysiological performance,
145 neurocognitive behavioral and psychometric measurements. The neurophysiological
146 performance metrics were derived from resting and active state neuroelectric imaging methods,
147 classic cognitive abilities task measures and from the Connor-Davidson Resilience Scale. Pre
148 and post behavioral (classic task scores) and neural performance markers (age-normed Power
149 Spectral Density (PSD) from resting state and event-related potentials) were obtained during the
150 evaluation. Resting state neurometrics were derived from two FDA-registered databases
151 (BrainDx, Neuroguide), using a z-score method to evaluate neurophysiological performance
152 metrics. Active event-related potential neurometrics and z-score decision training metrics were
153 obtained using a non-published proprietary database compiled from previous clinical and non-
154 clinical cases (developed by the lead author). Access to the proprietary database for conducting
155 neurometrics can be obtained by arrangement with the lead author at NTLGroup, Inc.

156 Figure 1 depicts the ten dependent (i.e., treatment) measures chosen from the Woodcock Johnson
157 Cognitive Abilities III Assessment Battery (WJIII) [65] and five additional neurocognitive task
158 measures derived from neurophysiological performance metrics. These measures were used to
159 aid in *rCRT* exercise selection and in evaluating post training effectiveness. The WJIII battery is a

160 set of cognitive ability sub-tests based on the Cattell-Horn-Carroll (CHC) theory of cognitive
161 abilities. The CHC theory provides a comprehensive framework for understanding the structure
162 of cognitive information processing and the cognitive abilities required to support proper
163 function. Five neurophysiological tasks were chosen to illuminate source-reconstructed neural
164 network metric performance. These tasks included eyes-closed and eyes-open resting states,
165 Flanker Task, Sternberg Working Memory Task and an Auditory Event Potential Task [66-72].

166 Neurophysical/NeuroCognitive (NeuroCodex[®]) Pre-Post Evaluation To obtain behavioral and
167 temporal neural performance metrics, CHC tasks were presented to participants by the EventID
168 task management program. Participants were seated in front of a computer screen and performed
169 a battery of tasks derived from the WJIII battery. Each participant performed the cognitive
170 battery while attached to a 19-channel EEG monitor (impedance below 5 kOhms) to record
171 neuroelectric measures of EEG during the testing activities. After artifact rejection was
172 performed on the EEG, behavioral and temporal neural metric measures were computed using
173 classical ICA/PCA methods to obtain metrics for each test listed in Figure 1. The testing
174 procedure began with a resting state eyes-closed and eyes-open condition as a baseline measure.
175 Classical age-normed neurometrics were obtained based on standardized resting state
176 quantitative EEG (qEEG) measures. These age-normed measures were included as baselines,
177 compared against active ERP task measures as outlined in Figure 1.

178 To further support changes in resilient function, neural metric performance measures were
179 obtained from five key source-reconstructed canonical networks that are considered to fine-tune
180 behavior under variable environmental conditions. These networks are implicated in maintaining
181 proper task performance and in general mental health preservation [67-73]. The program uses the
182 Gordon et al [69] description of three distinct sets of connector hubs which integrate brain

183 functional activities to model neurofunctional interactions. These three are Control-Default hubs,
184 Cross-Control Connector hubs and Control-Processing hubs.

185 The five key networks include: *Working Memory* - the primary network that supports reasoning,
186 expanded thought, and awareness by providing the mind a conscious workspace for information
187 [69,70]; *Cognitive Control Networks (CCN)* - cognitive control incorporates processes involved
188 in producing and preserving appropriate task goals, including suppressing irrelevant mental and
189 physical activities that distract from achieving the desired set of task [69,70]; *CCN Subdivisions:*
190 (1) *The Frontal-Parietal Network (FPN)* provides active online control, allowing it to adaptively
191 initiate and adjust control [69,70]; (2) the *Cingulate-Opercular Network (CON)* provides stable
192 'set-maintenance' (state maintenance) over the entire task epoch or behavioral strategy[69,70];
193 (3) the *Saliency Network (SN, the Attention Networks plus Insula Network)* is involved in rapid
194 detection of goal-relevant events and facilitation of access to appropriate cognitive resources by
195 interacting with multiple functional systems, thereby supporting a wide range of cognitive
196 processes[69,70]. The *Default Mode Network (DMN)* is implicated in the brain's default resting
197 state conditions and in its ability to sustain task performance. The DMN is composed of
198 functionally specialized subsystems, with the anterior DMN (i.e., medial Prefrontal Cortex
199 (PFC)) associated with identifying stimuli as self-salient, whereas the posterior DMN region
200 (with the parahippocampal gyrus) is involved in autobiographical search and memory retrieval.
201 Mechanisms within the DMN are implicated in regulating emotional reactivity and may play a
202 key role in the empathic process by establishing a distinction between other- and self- related
203 feelings [69-73]. Regarding congruent cognitive/behavioral health performance, a close
204 relationship exists between empathy and executive regulatory mechanisms. Sluggish and/or poor
205 (dis)engagement of the DMN is a noted biomarker within several mental health conditions,

206 including depression and attention deficit disorders [69,73]. The opposing relationship between
207 DMN and cognitive control networks may influence the ability to exert cognitive control [69,73]
208 and play an important role in the regulation of mind-wandering and rumination that impacts task
209 performance [73].

210 Fig 1. Neurocognitive Functions of Interest and Canonical Networks

211 Training Procedure Immediately after initial evaluation, participants used the NeuroCoach®
212 Training System three times per week for twelve weeks (approximately 30–40 minutes per
213 session); participants were then reassessed. All participants completed a non-verbal cognitive
214 enhancement/neuro-remodeling treatment program that monitors and evaluates a user’s defined
215 neural networks system performance status in real-time. Between 48 and 80 sessions of
216 extensive training (approximately 30–40 minutes per session) were completed before final re-
217 evaluations were completed. The training system is rooted in modern *r*CRT methods,
218 incorporating a neural network BCI monitoring interface. The BCI provides neural network
219 performance integrity metrics (*n*PIMs), originated from one or more of the three control
220 connector hub systems. The *n*PIMs inform the leveling training algorithm as it adjusts program
221 training intensity levels. The BCI adjusts the difficulty level for each training activity based on
222 *in-the-moment* brain performance metrics. Individual *n*PIMs are derived from the neural network
223 systems that support various cognitive functions being trained and are user-selectable. The *r*CRT
224 methodology is implemented through a selectable set of computer activities specific to individual
225 needs and engages the desired brain network systems and cognitive functions. Each activity is
226 based on classic neuroscience paradigms [60-69]. The BCI interface informs the trainer, the user,
227 the *r*CRT activity in real time the current neural network performance integrity status based on
228 the user’s present *n*PIMs state.

229 Each *r*CRT activity incorporates a performance leveling algorithm (PLA) to adjust the intensity
230 of the activity by rendering the pursuit to be either more or less intense. Unique in our method is
231 that the PLA encompasses both *n*PIMs and behavioral responses (e.g., response times, accuracy)
232 to adjust the level of intensity of the activity. This adjustment is based on the real-time
233 performance ability of the user, and targets the intensity required to properly engage long-term
234 potentiation (LTP) and long-term depreciation (LTD) network learning rules [75-83]. Difficulty
235 is adjusted based upon current responses, with the goal of a proper ratio of neurocircuit
236 engagement as opposed to a certain level of correct responses. The intention of the performance-
237 leveling algorithm is to adjust the level of pursuit play to a comfortable level, allowing the user
238 to progress through the activity successfully while simultaneously focusing on developing and/or
239 strengthening the performance integrity of the neural system being trained.

240 *NeuroCoach® Training Module Example and Description. The Split-Attention* application (a
241 NeuroCoach® training module) is an adaptive process-based, nonverbal training technique
242 designed to aid in re-setting/enhancing the attention (ATN), working memory (WMN), frontal
243 parietal (FPN) and salience networks (SN). Split-Attention uses a relaxation and restorative
244 framework that allows the trained networks to regain or obtain a natural homeostatic balance
245 needed to maintain a desired level of performance as it drives the user towards increased
246 capacity, neural efficiency and performance resilience. Neurobehaviorally, the application
247 focuses on training the useful field of view (visual attention), working memory, cognitive speed,
248 task switching, and multiple attention abilities, all in one application.

249
250 The lead author has used this application clinically for ten years with brain-injured and learning-
251 disabled populations. The application promotes a relaxed sustained attentional focus in

252 professional athletes and supports restorative cognitive enhancement. The Split-Attention
253 exercise satisfies The Institute of Medicine’s Checklist criteria for brain training [39].

254
255 Analysis of Pre- and Post-rCRT Scores Scoring data for all participants were pooled within a
256 Pandas data frame and analyzed as a batch for means, standard deviations and pre/post rCRT
257 changes by means of a Python script. P-values comparing pre/post rCRT subject scores were
258 calculated from entire population distributions by using the two-sided Kolmogorov-Smirnov
259 algorithm within SciPy. This method consistently produced more conservative (i.e., larger) p-
260 values than other methods which consider only population means and standard deviations.

261
262 Analysis of Practice Effects - RCI Calculations. The RCI technique used to correct for practice
263 effects and measurement error is defined as $((X_2 - X_1) - (M_2 - M_1)) / SDD$ [74,75] where X_1 is the
264 measured pretest score, X_2 the post-test score, SDD the standard deviation of the group test-
265 retest difference, M_1 the control group mean pretest score, and M_2 the control group mean post-
266 test score. As a retrospective chart review, the study did not use control subjects and therefore
267 obtaining measures of M_1 and M_2 are not directly available. However, several studies have
268 determined that the estimated change in cognitive test retest scores range between .25 and .33 of
269 a typical standard deviation [74-76]. Applied to standard scores, M_1 , M_2 values would range
270 between 3.75 and 5.0. Table 2 presents results for the 14 Woodcock Johnson Variables and the
271 RCI results from all tests.

272

273 **3.0 Results**

274

275 Subjects completed identical Woodcock Johnson III assessments before and after *r*CRT
276 treatment. The battery included fourteen assessments in the following areas: General Intellectual
277 Ability (GIA), Thinking Efficiency, Concept Formation, Working Memory, Numbers Reversed,
278 Visual Auditory Learning, Visual Audio Delayed, Verbal Ability, Phonemic Awareness, Verbal
279 Comprehension, Incomplete Words, Sound Blending, Spatial Relations and Visual Matching.
280 *r*CRT treatment explicitly targeted development in neurocircuits related to the first seven of
281 these areas but did not explicitly target development in the second seven areas. Given the
282 absence of a control group in this retrospective chart review study, measuring performance in
283 both targeted and untargeted areas provided some assessment of the magnitude of specific
284 treatment effects.

285
286 Table 2 summarizes the pre- and post-treatment results across all Woodcock Johnson III
287 assessments. Histograms of pre- and post-training scores for individual areas are available in
288 Supplementary Materials (Figures S1-S14). Notably, we observed significant improvements (p
289 values ranged from 10^{-4} to 10^{-22}) across all Woodcock Johnson III areas, as might be expected
290 after many sessions of intensive *r*CRT. To assess the differential impact of explicitly targeting an
291 area within the *r*CRT program, we adjusted these observed improvements to reflect the percent
292 change within each area, and compared the pooled percent changes observed in trained areas
293 against those observed for untrained areas. Figure 1 displays histograms for these pooled
294 changes. The mean percent change for trained areas was double that observed for untrained
295 areas, at 17.2% versus 8.3%, respectively. Figure 2 shows percent changes observed across each
296 area, ranked by magnitude, and highlights how consistently trained areas received a greater
297 percent change than those observed for untrained areas.

298

299 Table 1. Summary of the Pre- and Post-treatment Training Results

300

<i>Trained</i>	Pre-Mean (SD)	Post-Mean (SD)	Change (SD)	t Stat	P_{2tail}	Cohen's <i>d</i>	RCI pe3.75	RCI pe5.00
<i>General Intellectual Ability</i>	100.35 (12.73)	115.64 (12.78)	15.29 (7.67)	28.13	<.01	1.2	3.14	2.8
<i>Thinking Efficiency</i>	100.05 (15.32)	113.42 (14.89)	13.37 (10.03)	18.86	<.01	1.04	1.92	1.67
<i>Concept Formation</i>	102.42 (15.74)	113.17 (12.16)	10.75 (7.79)	13.41	<.01	1.18	1.36	1.12
<i>Working Memory</i>	102.08 (17.49)	117.21 (17.80)	15.13 (12.64)	16.94	<.01	1.04	1.8	1.67

312 **4.0 Discussion**

313

314 Previous mTBI CRT program meta-analyses report medium effect size training improvements
315 [75-77]. As such, the study authors recommend CRT methods as a viable method for treating
316 mTBIs [75-77]. Traditional mTBI treatment programs generally begin with neuropsychological
317 behavioral testing that do not include a neuroimaging exam. As a result, training is focused on
318 behavioral deficits found within attentional, memory, or other executive domains, without
319 considering possible neural network performance interruptions nor possible reduced neural
320 integrative effects. In contrast, this study explored possible neural network performance
321 interruptions by choosing training targets based on possible neural network performance
322 interruptions based on a standardized cognitive task-based neuroimaging exam. Additionally, to
323 support optimal network remodeling during *r*CRT training, each training activity was guided by
324 network performance nPIMs provided by a BCI interface in support of proper neural functional
325 remodeling needed to support resilient, flexible and adaptable behaviors. More expressly, the
326 *r*CRT training program focused on improving neural network functional performance to support
327 long-term potentiation (LTP) and long-term depreciation (LTD) network learning rules during
328 the training process.

329

330 Group level t-test and practice effect RCI value changes support significant positive changes
331 within important cognitive abilities' performance metrics known to support executive cognitive
332 control abilities needed in resilient, flexible and adaptable behavioral expressions. *r*CRT training
333 target selection focused on cognitive control training activities. We anticipated a positive training

334 effect to occur in the all measured cognitive domains due to general cognitive improvement in
335 cognitive network efficiency. However, we further expected a greater improvement in the
336 executive function metrics due to the focus in the training. Pre and post scores from seven
337 cognitive abilities considered dependent on executive cognitive control networks were compared
338 against seven non-executive control abilities and supported our expectations. We observed
339 significant improvements (p values 10^{-4} to 10^{-22}) with large Cohen's d effect sizes (.78-1.20)
340 across thirteen cognitive ability domains with a medium effect size (.49) on the remaining. The
341 mean percent change for pooled trained domain was double that observed for pooled untrained
342 domain, at 17.2% versus 8.3%, respectively. To further adjust for practice effects, practice effect
343 RCI values (based upon literature known adjustments) were computed and further supported the
344 effectiveness of the r CRT training (RCI- trained 1.4 - 4.8; untrained RCI .08-.75) on the
345 executive control networks.

346
347 In summary, this mTBI study demonstrates a strong possible increase in training effects over
348 conventional r CRT methods. This was achieved by first using a neuroelectric imaging exam
349 based on EEG source reconstructed neural network methods used in r CRT training target
350 selection. Second, we augmented individual r CRT activities with a BCI interface to monitor and
351 compute *in-the-moment* neural network performance integrity metrics (nPIMs) needed to align
352 the level of activity engagement. Activity level computations were required to properly manage
353 cognitive loads and to properly engage long-term potentiation (LTP) and long-term depreciation
354 (LTD) network learning rules. From our experience, this automated approach to classical r CRT
355 methods offers two extensions over traditional pen and pencil, or computer game CRT
356 approaches: 1) tailoring the selection of the r CRT training procedures based on neural network

357 performance metrics derived from EEG source reconstruction neuroelectric imaging evaluations
358 to isolate underlying neural network disruptions; 2) amplifying neural network regional training
359 by means of BCI treatment amplification.

360

361 In general, the training program assumes that coupling key, resilience-supporting neural circuits
362 with proper problem-solving skills promotes the emergence of resilient, adaptive behaviors.

363 Based upon program participant subjective reports, we found that in the context of daily living,
364 this emergence means proper brain based behavioral health expressions that allow return to
365 productive work, social reintegration and improvement in one's quality of life. In other contexts,
366 such as in sports, this emergence means increased sports performance for both injured and non-
367 injured athletes.

368

369 This retrospective chart review was limited by the lack of a control group, although comparing
370 explicitly trained versus untrained cognitive areas provided some measure of the effect of
371 treatment. Future work will further "mine" retrospective data to inform the design and focus of
372 controlled, prospective studies. In addition, customized individual rCRT programs will benefit
373 from the insights gleaned from analysis of our database of retrospective data.
