66 **ABSTRACT** We sequenced the genomes of 5,085 SARS-CoV-2 strains
67 causing two COVID-19 disease waves in metropolitan Houston, Texas, an
68 ethnically diverse region with seven million residents. The genomes were
69 from viruses recovered in the earliest recognized phase of the pandemic in
70 Houston, and an ongoing massive second wave of infections. The virus
71 was originally introduced into Houston many times independently. Virtually
72 all strains in the second wave have a Gly614 amino acid replacement in the
73 spike protein, a polymorphism that has been linked to increased
74 transmission and infectivity. Patients infected with the Gly614 variant
75 strains had significantly higher virus loads in the nasopharynx on initial
76 diagnosis. We found little evidence of a significant relationship between
77 virus genotypes and altered virulence, stressing the linkage between
78 disease severity, underlying medical conditions, and host genetics. Some
79 regions of the spike protein - the primary target of global vaccine efforts -
80 are replete with amino acid replacements, perhaps indicating the action of
81 selection. We exploited the genomic data to generate defined single amino
82 acid replacements in the receptor binding domain of spike protein that,
83 importantly, produced decreased recognition by the neutralizing
84 monoclonal antibody CR30022. Our study is the first analysis of the
85 molecular architecture of SARS-CoV-2 in two infection waves in a major
86 metropolitan region. The findings will help us to understand the origin,
87 composition, and trajectory of future infection waves, and the potential

88 **effect of the host immune response and therapeutic maneuvers on SARS-**
89 **CoV-2 evolution.**

90

91 **IMPORTANCE** There is concern about second and subsequent waves of
92 **COVID-19** caused by the SARS-CoV-2 coronavirus occurring in
93 **communities globally that had an initial disease wave. Metropolitan**
94 **Houston, Texas, with a population of 7 million, is experiencing a massive**
95 **second disease wave that began in late May 2020. To understand SARS-**
96 **CoV-2 molecular population genomic architecture, evolution, and**
97 **relationship between virus genotypes and patient features, we sequenced**
98 **the genomes of 5,085 SARS-CoV-2 strains from these two waves. Our study**
99 **provides the first molecular characterization of SARS-CoV-2 strains**
100 **causing two distinct COVID-19 disease waves.**

103 population genomics, evolution

104

105 [Introduction]

106 **P**andemic disease caused by the severe acute respiratory syndrome
107 coronavirus 2 (SARS-CoV-2) virus is now responsible for massive human
108 morbidity and mortality worldwide (1-5). The virus was first documented to cause
109 severe respiratory infections in Wuhan, China, beginning in late December 2019
110 (6-9). Global dissemination occurred extremely rapidly and has affected major
111 population centers on most continents (10, 11). In the United States, the Seattle
112 and the New York City (NYC) regions have been especially important centers of
113 COVID-19 disease caused by SARS-CoV-2. For example, as of August 19,
114 2020, there were 227,419 confirmed SARS-CoV-2 cases in NYC, causing 56,831
115 hospitalizations and 19,005 confirmed fatalities and 4,638 probable fatalities (12).
116 Similarly, in Seattle and King County, 17,989 positive patients and 696 deaths
117 have been reported as of August 18, 2020 (13).

118 The Houston metropolitan area is the fourth largest and most ethnically
119 diverse city in the United States, with a population of approximately 7 million
120 (14, 15). The 2,400-bed Houston Methodist health system has seven hospitals
121 and serves a large, multiethnic, and socioeconomically diverse patient population
122 throughout greater Houston (13, 14). The first COVID-19 case in metropolitan
123 Houston was reported on March 5, 2020 with community spread occurring one
124 week later (16). Many of the first cases in our region were associated with
125 national or international travel in areas known to have SARS-CoV-2 virus
126 outbreaks (16). A central molecular diagnostic laboratory serving all Houston
127 Methodist hospitals and our very early adoption of a molecular test for the SARS-

128 CoV-2 virus permitted us to rapidly identify positive patients and interrogate
129 genomic variation among strains causing early infections in the greater Houston
130 area. Our analysis of SARS-CoV-2 genomes causing disease in Houston has
131 continued unabated since early March and is ongoing. Genome sequencing and
132 related efforts were expanded extensively in late May as we recognized that a
133 prominent second wave was underway (**Figure 1**).

134 Here, we report that SARS-CoV-2 was introduced to the Houston area
135 many times, independently, from diverse geographic regions, with virus
136 genotypes representing genetic clades causing disease in Europe, Asia, South
137 America and elsewhere in the United States. There was widespread community
138 dissemination soon after COVID-19 cases were reported in Houston. Strains with
139 a Gly614 amino acid replacement in the spike protein, a polymorphism that has
140 been linked to increased transmission and *in vitro* cell infectivity, increased
141 significantly over time and caused virtually all COVID-19 cases in the massive
142 second disease wave. Patients infected with strains with the Gly614 variant had
143 significantly higher virus loads in the nasopharynx on initial diagnosis. Some
144 naturally occurring single amino acid replacements in the receptor binding
145 domain of spike protein resulted in decreased reactivity with a neutralizing
146 monoclonal antibody, consistent with the idea that some virus variants arise due
147 to host immune pressure.

148

149 **RESULTS**

150 **Description of metropolitan Houston.** Houston, Texas, is located in the
151 southwestern United States, 50 miles inland from the Gulf of Mexico. It is the
152 most ethnically diverse city in the United States (14). Metropolitan Houston is
153 comprised predominantly of Harris County plus parts of eight contiguous
154 surrounding counties. In the aggregate, the metropolitan area includes 9,444
155 square miles. The estimated population size of metropolitan Houston is 7 million
156 (<https://www.houston.org/houston-data>).

157 **Epidemic curve characteristics over two disease waves.** The first
158 confirmed case of COVID-19 in the Houston metropolitan region was reported on
159 March 5, 2020 (16), and the first confirmed case diagnosed in Houston Methodist
160 hospitals was reported on March 6, 2020. The epidemic curve indicated a first
161 wave of COVID-19 cases that peaked around April 11-15, followed by a decline
162 in cases until May 11. Soon thereafter, the slope of the case curve increased with
163 a very sharp uptick in confirmed cases beginning on June 12 (**Figure 1B**). We
164 consider May 11 as the transition between waves, as this date is the inflection
165 point of the cumulative new cases curve and had the absolute lowest number of
166 new cases in the mid-May time period. Thus, for the data presented herein, wave
167 1 is defined as March 5 through May 11, 2020, and wave 2 is defined as May 12
168 through July 7, 2020. Epidemiologic trends within the Houston Methodist Hospital
169 population were mirrored by data from Harris County and the greater
170 metropolitan Houston region (**Figure 1A**). Through the 7th of July, 25,366
171 COVID-19 cases were reported in Houston, 37,776 cases in Harris County, and
172 53,330 in metropolitan Houston, including 9,823 cases in Houston Methodist

173 facilities (inpatients and outpatients) (<https://www.tmc.edu/coronavirus->
174 [updates/infection-rate-in-the-greater-houston-area/](https://www.tmc.edu/coronavirus-) and
175 <https://harriscounty.maps.arcgis.com/apps/opstdashboard/index.html#/c0de71f8e>
176 [a484b85bb5efcb7c07c6914](https://harriscounty.maps.arcgis.com/apps/opstdashboard/index.html#/c0de71f8e)).

177 During the first wave (early March through May 11), 11,476 COVID-19
178 cases were reported in Houston, including 1,729 cases in the Houston Methodist
179 Hospital system. Early in the first wave (from March 5 through March 30, 2020),
180 we tested 3,080 patient specimens. Of these, 406 (13.2%) samples were positive
181 for SARS-CoV-2, representing 40% (358/898) of all confirmed cases in
182 metropolitan Houston during that time period. As our laboratory was the first
183 hospital-based facility to have molecular testing capacity for SARS-CoV-2
184 available on site, our strain samples are likely representative of COVID-19
185 infections during the first wave.

186 For the entire study period (March 5 through July 7, 2020), we tested
187 68,418 specimens from 55,800 patients. Of these, 9,121 patients (16.4%) had a
188 positive test result, representing 17.1% (9,121/53,300) of all confirmed cases in
189 metropolitan Houston. Thus, our strain samples are also representative of those
190 responsible for COVID-19 infections in the massive second wave.

191 To test the hypothesis that, on average, the two waves affected different
192 groups of patients, we analyzed individual patient characteristics (hospitalized
193 and non-hospitalized) in each wave. Consistent with this hypothesis, we found
194 significant differences in the COVID-19 patients in each wave (**Table S1**). For
195 example, patients in the second wave were significantly younger, had fewer

196 comorbidities, were more likely to be Hispanic/Latino (by self-report), and lived in
197 zip codes with lower median incomes (**Table S1**). A detailed analysis of the
198 characteristics of patients hospitalized in Houston Methodist facilities in the two
199 waves has recently been published (17).

200 **SARS-CoV-2 genome sequencing and phylogenetic analysis.** To
201 investigate the genomic architecture of the virus across the two waves, we
202 sequenced the genomes of 5,085 SARS-CoV-2 strains dating to the earliest time
203 of confirmed COVID-19 cases in Houston. Analysis of SARS-CoV-2 strains
204 causing disease in the first wave (March 5 through May 11) identified the
205 presence of many diverse virus genomes that, in the aggregate, represent the
206 major clades identified globally to date (**Figure 1B**). Clades G, GH, GR, and S
207 were the four most abundantly represented phylogenetic groups (**Figure 1B**).
208 Strains with the Gly614 amino acid variant in spike protein represented 82% of
209 the SARS-CoV-2 strains in wave 1, and 99.9% in wave 2 ($p < 0.0001$; Fisher's
210 exact test) (**Figure 1B**). This spike protein variant is characteristic of clades G,
211 GH, and GR. Importantly, strains with the Gly614 variant represented only 71%
212 of the specimens sequenced in March, the early part of wave 1 (**Figure 1B**). We
213 attribute the decrease in strains with this variant observed in the first two weeks
214 of March (**Figure 1B**) to fluctuation caused by the relatively fewer COVID-19
215 cases occurring during this period.

216 **Relating spatiotemporal genome analysis with virus genotypes over**
217 **two disease waves.** We examined the spatial and temporal mapping of genomic
218 data to investigate community spread during wave 1 (**Figure 2**). Rapid and

219 widespread community dissemination occurred soon after the initial COVID-19
220 cases were reported in Houston. The heterogenous virus genotypes present very
221 early in wave 1 indicate that multiple strains independently entered metropolitan
222 Houston, rather than introduction and spread of a single strain. An important
223 observation was that strains of most of the individual subclades were distributed
224 over broad geographic areas (**Figure S1**). These findings are consistent with the
225 known ability of SARS-CoV-2 to spread very rapidly from person to person.

226 **Relationship between virus clades, clinical characteristics of infected**
227 **patients, and additional metadata.** It is possible that SARS-CoV-2 genome
228 subtypes have different clinical characteristics, analogous to what is believed to
229 have occurred with Ebola virus (18-20) and known to occur for other pathogenic
230 microbes (21). As an initial examination of this issue in SARS-CoV-2, we tested
231 the hypothesis that patients with disease severe enough to warrant
232 hospitalization were infected with a non-random subset of virus genotypes. We
233 also examined the association between virus clades and disease severity based
234 on overall mortality, highest level of required care (intensive care unit,
235 intermediate care unit, inpatient or outpatient), need for mechanical ventilation,
236 and length of stay. There was no simple relationship between virus clades and
237 disease severity using these four indicators. Similarly, there was no simple
238 relationship between virus clades and other metadata, such as sex, age, or
239 ethnicity (**Figure S2**).

240 **Machine learning analysis.** Machine learning models can be used to
241 identify complex relationships not revealed by statistical analyses. We built

242 machine learning models to test the hypothesis that virus genome sequence can
243 predict patient outcomes including mortality, length of stay, level of care, ICU
244 admission, supplemental oxygen use, and mechanical ventilation. Models to
245 predict outcomes based on virus genome sequence alone resulted in low F1
246 scores less than 50% (0.41 – 0.49) and regression models showed similarly low
247 R^2 values (-0.01 – -0.20) (**Table S2**). F1 scores near 50% are indicative of
248 classifiers that are performing similarly to random chance. The use of patient
249 metadata alone to predict patient outcome improved the model's F1 scores by 5-
250 10% (0.51 – 0.56) overall. The inclusion of patient metadata with virus genome
251 sequence data improved most predictions of outcomes, compared to genome
252 sequence alone, to 50% to 55% F1 overall (0.42 – 0.55) in the models (**Table**
253 **S2**). The findings are indicative of two possibilities that are not mutually
254 exclusive. First, patient metadata, such as age and sex, may provide more signal
255 for the model to use and thus result in better accuracies. Second, the model's
256 use of single nucleotide polymorphisms (SNPs) may have resulted in overfitting.
257 Most importantly, no SNP predicted a significant difference in outcome. A table of
258 classifier accuracy scores and performance information is provided in **Table S2**.

259 **Patient outcome and metadata correlations.** Overall, very few metadata
260 categories correlated with patient outcomes (**Table S3**). Mortality was
261 independently correlated with both Rh factor-positive blood type and increasing
262 age, with Pearson correlation coefficients (PCC) equal to 0.22 and 0.27,
263 respectively. This means that 22-27% of the variation in mortality can be
264 predicted from Rh factor-positive blood type and patient age, respectively. Length

265 of stay correlated independently with increasing age (PCC=0.20). Positive Rh
266 factor also correlated with ICU length of stay (PCC=0.20). All other patient
267 metadata correlations to outcomes had PCC less than 0.20 (**Table S3**).

268 We further analyzed outcomes correlated to isolates from wave 1 and 2,
269 and the presence of the Gly614 variant in spike protein. Being in wave 1 was
270 independently correlated with mechanical ventilation days, overall length of stay,
271 and ICU length of stay, with PCC equal to 0.20, 0.18, and 0.14, respectively.
272 Importantly, the presence of the Gly614 variant did not correlate with patient
273 outcomes (**Table S3**).

274 **Analysis of the *nsp12* polymerase gene.** The SARS-CoV-2 genome
275 encodes an RNA-dependent RNA polymerase (RdRp, also referred to as Nsp12)
276 used in virus replication (22-25). Two amino acid substitutions (Phe479Leu and
277 Val556Leu) in RdRp each confer significant resistance *in vitro* to remdesivir, an
278 adenosine analog (26). Remdesivir is inserted into RNA chains by RdRp during
279 replication, resulting in premature termination of RNA synthesis and inhibition of
280 virus replication. This compound has shown prophylactic and therapeutic benefit
281 against MERS-CoV and SARS-CoV-2 experimental infection in rhesus
282 macaques (27, 28). Recent reports indicate that remdesivir has therapeutic
283 benefit in some COVID-19 hospitalized patients (29-33), leading it to be now
284 widely used in patients worldwide. Thus, it may be important to understand
285 variation in RdRp in large strain samples.

286 To acquire data about allelic variation in the *nsp12* gene, we analyzed our
287 5,085 virus genomes. The analysis identified 265 SNPs, including 140

288 nonsynonymous (amino acid-altering) SNPs, resulting in amino acid
289 replacements throughout the protein (**Table 1, Figure 3, Figure 4, Figure S3,**
290 **and Figure S4**). The most common amino acid change was Pro322Leu,
291 identified in 4,893 of the 5,085 (96%) patient isolates. This amino acid
292 replacement is common in genomes from clades G, GH, and GR, which are
293 distinguished from other SARS-CoV-2 clades by the presence of the Gly614
294 amino acid change in the spike protein. Most of the other amino acid changes in
295 RdRp were present in relatively small numbers of strains, and some have been
296 identified in other isolates in a publicly available database (34). Five prominent
297 exceptions included amino acid replacements: Ala15Val in 138 strains, Met462Ile
298 in 59 strains, Met600Ile in 75 strains, Thr907Ile in 45 strains, and Pro917Ser in
299 80 strains. All 75 Met600Ile strains were phylogenetically closely related
300 members of clade G, and also had the Pro322Leu amino acid replacement
301 characteristic of this clade (**Figure S3**). These data indicate that the Met600Ile
302 change is likely the evolved state, derived from a precursor strain with the
303 Pro322Leu replacement. Similarly, we investigated phylogenetic relationships
304 among strains with the other four amino acid changes noted above. In all cases,
305 the vast majority of strains with each amino acid replacement were found among
306 individual subclades of strains (**Figure S3**).

307 Importantly, none of the observed amino acid polymorphisms in RdRp
308 were located precisely at two sites known to cause *in vitro* resistance to
309 remdesivir (26). Most of the amino acid changes are located distantly from the
310 RNA-binding and catalytic sites (**Figure S4 and Table 1**). However,

311 replacements at six amino acid residues (Ala442Val, Ala448Val, Ala553Pro/Val,
312 Gly682Arg, Ser758Pro, and Cys812Phe) may potentially interfere with either
313 remdesivir binding or RNA synthesis. Four (Ala442Val, Ala448Val,
314 Ala553Pro/Val, and Gly682Arg) of the six substitution sites are located
315 immediately above the nucleotide-binding site, that is comprised of Lys544,
316 Arg552, and Arg554 residues as shown by structural studies (**Figure 4**). The
317 positions of these four variant amino acid sites are comparable to Val556 (**Figure**
318 **4**), for which a Val556Leu mutation in SARS-CoV was identified to confer
319 resistance to remdesivir *in vitro* (26). The other two substitutions (Ser758Pro and
320 Cys812Phe) are inferred to be located either at, or in the immediate proximity of,
321 the catalytic active site, that is comprised of three contiguous residues (Ser758,
322 Asp759, and Asp760). A proline substitution we identified at Ser758 (Ser758Pro)
323 is likely to negatively impact RNA synthesis. Although Cys812 is not directly
324 involved in the catalysis of RNA synthesis, it is only 3.5 Å away from Asp760.
325 The introduction of the bulkier phenylalanine substitution at Cys812 (Cys812Phe)
326 may impair RNA synthesis. Consequently, these two substitutions are expected
327 to detrimentally affect virus replication or fitness.

328 **Analysis of the gene encoding the spike protein.** The densely glycosylated
329 spike protein of SARS-CoV-2 and its close coronavirus relatives binds directly to
330 host-cell angiotensin-converting enzyme 2 (ACE2) receptors to enter host cells
331 (35-37). Thus, the spike protein is a major translational research target, including
332 intensive vaccine and therapeutic antibody (35-64). Analysis of the gene
333 encoding the spike protein identified 470 SNPs, including 285 that produce

334 amino acid changes (**Table 2, Figure 5**). Forty-nine of these replacements
335 (V11A, T51A, W64C, I119T, E156Q, S205A, D228G, L229W, P230T, N234D,
336 I235T, T274A, A288V, E324Q, E324V, S325P, S349F, S371P, S373P, T385I,
337 A419V, C480F, Y495S, L517F, K528R, Q628E, T632I, S708P, T719I, P728L,
338 S746P, E748K, G757V, V772A, K814R, D843N, S884A, M902I, I909V, E918Q,
339 S982L, M1029I, Q1142K, K1157M, Q1180R, D1199A, C1241F, C1247G, and
340 V1268A) are not represented in a publicly available database (34) as of August
341 19, 2020. Interestingly, 25 amino acid sites have three distinct variants (that is,
342 the reference amino acid plus two additional variant amino acids), and five amino
343 acid sites (amino acid positions 21, 27, 228, 936, and 1050) have four distinct
344 variants represented in our sample of 5,085 genomes (**Table 2, Figure 5**).

345 We mapped the location of amino acid replacements onto a model of the
346 full-length spike protein (35, 65) and observed that the substitutions are found in
347 each subunit and domain of the spike (**Figure 6**). However, the distribution of
348 amino acid changes is not uniform throughout the protein regions. For example,
349 compared to some other regions of the spike protein, the receptor binding
350 domain (RBD) has relatively few amino acid changes, and the frequency of
351 strains with these substitutions is low, each occurring in fewer than 10 isolates.
352 This finding is consistent with the functional constraints on RBD to mediate
353 interaction with ACE2. In contrast, the periphery of the S1 subunit NTD contains
354 a dense cluster of substituted residues, with some single amino acid
355 replacements found in 10–20 isolates (**Table 2, Figure 5, Figure 6**). Clustering
356 of amino acid changes in a distinct region of the spike protein may be a signal of

357 positive selection. Inasmuch as infected patients make antibodies against the
358 NTD, we favor the idea that host immune selection is one force contributing to
359 some of the amino acid variation in this region. One NTD substitution, H49Y, was
360 found in 142 isolates. This position is not well exposed on the surface of the NTD
361 and is likely not a result of immune pressure. The same is true for another highly
362 represented substitution, F1052L. This substitution was observed in 167 isolates,
363 and F1052 is buried within the core of the S2 subunit. The substitution observed
364 most frequently in the spike protein in our sample is D614G, a change observed
365 in 4,895 of the isolates. As noted above, strains with the Gly614 variant
366 significantly increased in wave 2 compared to wave 1.

367 As observed with RdRp, the majority of strains with each single amino
368 acid change in the spike protein were found on a distinct phylogenetic lineage
369 (**Figure S5**), indicating identity by descent. A prominent exception is the
370 Leu5Phe replacement that is present in all major clades, suggesting that this
371 amino acid change arose multiple times independently or very early in the course
372 of SARS-CoV-2 evolution. Finally, we note that examination of the phylogenetic
373 distribution of strains with multiple distinct amino acid replacements at the same
374 site (e.g., Arg21Ile/Lys/Thr, Ala27Ser/Thr/Val, etc.) revealed that they were
375 commonly found in different genetic branches, consistent with independent origin
376 (**Figure S5**).

377 **Cycle threshold (Ct) comparison of SARS-CoV-2 strains with either**
378 **the Asp614 or Gly614 amino acid replacements in spike protein.** It has been
379 reported that patients infected with strains having spike protein Gly614 variant

380 have, on average, higher virus loads on initial diagnosis (66-70). To determine if
381 this is the case in Houston strains, we examined the cycle threshold (Ct) for
382 every sequenced strain that was detected from a patient specimen using the
383 SARS-CoV-2 Assay done by the Hologic Panther instrument. We identified a
384 significant difference ($p < 0.0001$) between the mean Ct value for strains with an
385 Asp614 ($n=102$) or Gly614 ($n=812$) variant of the spike protein (**Figure 7**).
386 Strains with Gly614 had a Ct value significantly lower than strains with the
387 Asp614 variant, indicating that patients infected with the Gly614 strains had, on
388 average, higher virus loads on initial diagnosis than patients infected by strains
389 with the Asp614 variant (**Figure 7**). This observation is consistent with the
390 conjecture that, on average, strains with the Gly614 variant are better able to
391 disseminate.

392 **Characterization of recombinant proteins with single amino acid**
393 **replacements in the receptor binding domain region of spike protein.** The
394 RBD of spike protein binds the ACE2 surface receptor and is also targeted by
395 neutralizing (36, 37, 41, 43-46, 48-62, 71). Thus, single amino acid replacements
396 in this domain may have functional consequences that enhance virus fitness. To
397 begin to test this idea, we expressed spike variants with the Asp614Gly
398 replacement and 13 clinical RBD variants identified in our genome sequencing
399 studies (**Figure 8, Table S4, S5**). All RBD variants were cloned into an
400 engineered spike protein construct that stabilizes the prefusion state and
401 increases overall expression yield (spike-6P, here referred to as spike) (64).

402 We first assessed the biophysical properties of spike-Asp614Gly, an
403 amino acid polymorphism that is common globally and increased significantly in
404 our wave 2 strain isolates. Pseudotyped viruses expressing spike-Gly614 have
405 higher infectivity for host cells *in vitro* than spike-Asp614 (66, 67, 69, 72, 73). The
406 higher infectivity of spike-Gly614 is correlated with increased stability and
407 incorporation of the spike protein into the pseudovirion (73). We observed a
408 higher expression level (**Figure 8A, B**) and increased thermostability for the
409 spike protein construct containing this variant (**Figure 8C, D**). The size exclusion
410 chromatography (SEC) elution profile of spike-Asp614 was indistinguishable from
411 spike-Gly614, consistent with a trimeric conformation (**Figure 8A**). These results
412 are broadly consistent with higher-resolution structural analyses of both spike
413 variants.

414 Next, we purified and biophysically characterized 13 RBD mutants that
415 each contain Gly614 and one additional single amino acid replacement we
416 identified by genome sequencing our clinical samples (**Table S6**). All variants
417 eluted as trimers, indicating the global structure, remained intact (**Figure 8** and
418 **Figure S6**). However, several variants had reduced expression levels and
419 virtually all had decreased thermostability relative to the variant that had only a
420 D614G single amino acid replacement (**Figure 8D**). The A419V and A522V
421 mutations were especially deleterious, reducing yield and precluding further
422 downstream analysis (**Figure 8B**). We next assayed the affinity of the 11 highest-
423 expressing spike variants for ACE2 and the neutralizing monoclonal antibody
424 CR3022 via enzyme-linked immunosorbent assays (ELISAs) (**Figure 8E-G** and

425 **Table S6**). Most variants retained high affinity for the ACE2 surface receptor.
426 However, importantly, three RBD variants (F338L, S373P, and R408T) had
427 substantially reduced affinity for CR3022, a monoclonal antibody that disrupts the
428 spike protein homotrimerization interface (63, 74). Notably, the S373P mutation
429 is one amino acid away from the epitope recognized by CR3022. These results
430 are consistent with the interpretation that some RBD mutants arising in COVID-
431 19 patients may have increased ability to escape humoral immune pressure, but
432 otherwise retain strong ACE2 binding affinity.

433

434 **DISCUSSION**

435 In this work we analyzed the molecular population genomics, sociodemographic,
436 and medical features of two waves of COVID-19 disease occurring in
437 metropolitan Houston, Texas, between early March and early July 2020. We also
438 studied the biophysical and immunologic properties of some naturally occurring
439 single amino acid changes in the spike protein RBD identified by sequencing the
440 5,085 genomes. We discovered that the first COVID-19 wave was caused by a
441 heterogenous array of virus genotypes assigned to several different clades. The
442 majority of cases in the first wave are related to strains that caused widespread
443 disease in European and Asian countries, as well as other localities. We
444 conclude that the SARS-CoV-2 virus was introduced into Houston many times
445 independently, likely by individuals who had traveled to or from different parts of
446 the world, including other communities in the United States. In support of this
447 conclusion, the first cases in metropolitan Houston were associated with a travel

448 history to a known COVID-19 region (16). The data are consistent with the fact
449 that Houston is a large international city characterized by a multi-ethnic
450 population and is a prominent transport hub with direct flights to major cities
451 globally.

452 The second wave of COVID-19 cases also is characterized by SARS-
453 CoV-2 strains with diverse genotypes. Virtually all cases in the second and
454 ongoing disease wave were caused by strains with the Gly614 variant of spike
455 protein (**Figure 1B**). Our data unambiguously demonstrate that strains with the
456 Gly614 variant increased significantly in frequency in wave 2 relative to wave 1 in
457 the Houston metropolitan region. This shift occurred very rapidly in a matter of
458 just a few months. Amino acid residue Asp614 is located in subdomain 2 (SD-2)
459 of the spike protein and forms a hydrogen bond and electrostatic interaction with
460 two residues in the S2 subunit of a neighboring protomer. Replacement of
461 aspartate with glycine would eliminate both interactions, thereby substantively
462 weakening the contact between the S1 and S2 subunits. We previously
463 speculated (75) that this weakening produces a more fusogenic spike protein, as
464 S1 must first dissociate from S2 before S2 can refold and mediate fusion of virus
465 and cell membranes. Stated another way, virus strains with the Gly614 variant
466 may be better able to enter host cells, potentially resulting in enhanced spread.
467 Consistent with this idea, Korber et al. (66) showed that the Gly614 variant grows
468 to higher titer as pseudotyped virions. On initial diagnosis infected individuals had
469 lower RT-PCR cycle thresholds suggesting higher upper respiratory tract viral
470 loads. Our data (**Figure 7**) are fully consistent with that finding Zhang et al. (73)

471 reported that pseudovirus with the 614Gly variant infected ACE2-expressing cells
472 more efficiently than the 614Asp. Similar results have been described by Hu et
473 al. (67) and Lorenzo-Redondo et al. (68). Plante et al. (76) recently studied
474 isogenic mutant SARS-CoV-2 strains with either the 614Asp or 614Gly variant
475 and found that the 614Gly variant virus had significantly increased replication in
476 human lung epithelial cells *in vitro* and increased infectious titers in nasal and
477 trachea washes obtained from experimentally infected hamsters. These results
478 are consistent with the idea that the 614Gly variant bestows increased virus
479 fitness in the upper respiratory tract (76).

480 Additional work is needed to investigate the potential biomedical relevance
481 and public health importance of the Asp614Gly polymorphism, including but not
482 limited to virus dissemination, overall fitness, impact on clinical course and
483 virulence, and development of vaccines and therapeutics. Although it is possible
484 that stochastic processes alone may account for the rapid increase in COVID-19
485 disease frequency caused by viruses containing the Gly614 variant, we do not
486 favor that interpretation in part because of the cumulative weight of the
487 epidemiologic, human RT-PCR diagnostics data, *in vitro* experimental findings,
488 and animal infection studies using isogenic mutant virus strains. In addition, if
489 stochastic processes solely are responsible, we believe it is difficult to explain
490 essentially simultaneous increase in frequency of the Gly614 variant in
491 genetically diverse viruses in three distinct clades (G, GH, and GR) in a
492 geographically large metropolitan area with 7 million ethnically diverse people.
493 Regardless, more research on this important topic is warranted.

494 Several groups have analyzed the relationship between human genetics,
495 blood types, and patient outcomes (33, 34, 77-80). In this regard, we identified a
496 correlation between Rh factor-positive blood type and increased mortality and
497 length of ICU stay. (Supplemental Table 3). Thus, our data are consistent with
498 studies suggesting that there are host genetic factors that contribute to disease
499 severity and outcome. More research is required to address the important
500 possibility.

501 The diversity present in our 1,026 virus genomes from the first disease
502 wave contrasts somewhat with data reported by Gonzalez-Reiche et al., who
503 studied 84 SARS-CoV-2 isolates causing disease in patients in the New York
504 City region (11). Those investigators concluded that the vast majority of disease
505 was caused by progeny of strains imported from Europe. Similarly, Bedford et al.
506 (10) reported that much of the COVID-19 disease in the Seattle, Washington
507 area was caused by strains that are progeny of a virus strain recently introduced
508 from China. Some aspects of our findings are similar to those reported recently
509 by Lemieux et al. based on analysis of strains causing disease in the Boston
510 area (81). Our findings, like theirs, highlight the importance of multiple
511 importation events of genetically diverse strains in the epidemiology of COVID-19
512 disease in this pandemic. Similarly, Icelandic and Brazilian investigators
513 documented that SARS-CoV-2 was imported by individuals traveling to or from
514 many European and other countries (82, 83).

515 The virus genome diversity and large sample size in our study permitted
516 us to test the hypothesis that distinct virus clades were nonrandomly associated

517 with hospitalized COVID-19 patients or disease severity. We did not find
518 evidence to support this hypothesis, but our continuing study of COVID-19 cases
519 accruing in the second wave will further improve statistical stratification.

520 We used machine learning classifiers to identify if any SNPs contribute to
521 increased infection severity or otherwise affect virus-host outcome. The models
522 could not be trained to accurately predict these outcomes from the available virus
523 genome sequence data. This may be due to sample size or class imbalance.
524 However, we do not favor this interpretation. Rather, we think that the inability to
525 identify particular virus SNPs predictive of disease severity or infection outcome
526 likely reflects the substantial heterogeneity in underlying medical conditions and
527 treatment regimens among COVID-19 patients studied herein. An alternative but
528 not mutually exclusive hypothesis is that patient genotypes play an important role
529 in determining virus-human interactions and resulting pathology. Although some
530 evidence has been presented in support of this idea (84, 85), available data
531 suggest that in the aggregate, host genetics does not play an overwhelming role
532 in determining outcome in the great majority of adult patients, once virus infection
533 is established.

534 Remdesivir is a nucleoside analog reported to have activity against
535 MERS-CoV, a coronavirus related to SARS-CoV-2. Recently, several studies
536 have reported that remdesivir shows promise in treating COVID-19 patients (29-
537 33), leading the FDA to issue an emergency use authorization. Because *in vitro*
538 resistance of SARS-CoV to remdesivir has been reported to be caused by either
539 of two amino acid replacements in RdRp (Phe479Leu or Val556Leu), we

540 interrogated our data for polymorphisms in the *nsp12* gene. Although we
541 identified 140 different inferred amino acid replacements in RdRp in the 5,085
542 genomes analyzed, none of these were located precisely at the two positions
543 associated with *in vitro* resistance to remdesivir. Inasmuch as remdesivir is now
544 being deployed widely to treat COVID-19 patients in Houston and elsewhere, our
545 findings suggest that the majority of SARS-CoV-2 strains currently circulating in
546 our region should be susceptible to this drug.

547 The amino acid replacements Ala442Val, Ala448Val, Ala553Pro/Val, and
548 Gly682Arg that we identified occur at sites that, intriguingly, are located directly
549 above the nucleotide substrate entry channel and nucleotide binding residues
550 Lys544, Arg552, and Arg554 (22, 23) (**Figure 4**). One possibility is that
551 substitution of the smaller alanine or glycine residues with the bulkier side chains
552 of Val/Pro/Arg may impose structural constraints for the modified nucleotide
553 analog to bind, and thereby disfavor remdesivir binding. This, in turn, may lead to
554 reduced incorporation of remdesivir into the nascent RNA, increased fidelity of
555 RNA synthesis, and ultimately drug resistance. A similar mechanism has been
556 proposed for a Val556Leu change (23).

557 We also identified one strain with a Lys477Asn replacement in RdRp. This
558 substitution is located close to a Phe479Leu replacement reported to produce
559 partial resistance to remdesivir *in vitro* in SARS-CoV patients from 2004,
560 although the amino acid positions are numbered differently in SARS-CoV and
561 SARS-CoV-2. Structural studies have suggested that this amino acid is surface-
562 exposed, and distant from known key functional elements. Our observed

563 Lys477Asn change is also located in a conserved motif described as a finger
564 domain of RdRp (**Figure 3 and 4**). One speculative possibility is that Lys477 is
565 involved in binding a yet unidentified cofactor such as Nsp7 or Nsp8, an
566 interaction that could modify nucleotide binding and/or fidelity at a distance.
567 These data warrant additional study in larger patient cohorts, especially in
568 individuals treated with remdesivir.

569 Analysis of the gene encoding the spike protein identified 285 polymorphic
570 amino acid sites relative to the reference genome, including 49 inferred amino
571 acid replacements not present in available databases as of August 19, 2020.
572 Importantly, 30 amino acid sites in the spike protein had two or three distinct
573 replacements relative to the reference strain. The occurrence of multiple variants
574 at the same amino acid site is one characteristic that may suggest functional
575 consequences. These data, coupled with structural information available for
576 spike protein, raise the possibility that some of the amino acid variants have
577 functional consequences, for example including altered serologic reactivity and
578 shown here. These data permit generation of many biomedically relevant
579 hypotheses now under study.

580 A recent study reported that RBD amino acid changes could be selected
581 *in vitro* using a pseudovirus neutralization assay and sera obtained from
582 convalescent plasma or monoclonal antibodies (86). The amino acid sites
583 included positions V445 and E484 in the RBD. Important to note, variants G446V
584 and E484Q were present in our patient samples. However, these mutations
585 retain high affinity to CR3022 (**Figure 8F, G**). The high-resolution structure of the

586 RBD/CR3022 complex shows that CR3022 makes contacts to residues 369-386,
587 380-392, and 427-430 of RBD (74). Although there is no overlap between
588 CR3022 and ACE2 epitopes, CR3022 is able to neutralize the virus through an
589 allosteric effect. We found that the Ser373Pro change, which is located within the
590 CR3022 epitope, has reduced affinity to CR3022 (**Figure 8F, G**). The F338L and
591 R408T mutations, although not found directly within the interacting epitope, also
592 display reduced binding to CR3022. Other investigators (86) using *in vitro*
593 antibody selection identified a change at amino acid site S151 in the N-terminal
594 domain, and we found mutations S151N and S151I in our patient samples. We
595 also note that two variant amino acids (Gly446Val and Phe456Leu) we identified
596 are located in a linear epitope found to be critical for a neutralizing monoclonal
597 antibody described recently by Li et al. (87).

598 In the aggregate, these findings suggest that mutations emerging within
599 the spike protein at positions within and proximal to known neutralization
600 epitopes may result in escape from antibodies and other therapeutics currently
601 under development. Importantly, our study did not reveal that these mutant
602 strains had disproportionately increased over time. The findings may also bear
603 on the occurrence of multiple amino acid substitutions at the same amino acid
604 site that we identified in this study, commonly a signal of selection. In the
605 aggregate, the data support a multifaceted approach to serological monitoring
606 and biologics development, including the use of monoclonal antibody cocktails
607 (46, 47, 88).

608

609 **CONCLUDING STATEMENT**

610 Our work represents analysis of the largest sample to date of SARS-CoV-2
611 genome sequences from patients in one metropolitan region in the United States.
612 The investigation was facilitated by the fact that we had rapidly assessed a
613 SARS-CoV-2 molecular diagnostic test in January 2020, more than a month
614 before the first COVID-19 patient was diagnosed in Houston. In addition, our
615 large healthcare system has seven hospitals and many facilities (e.g., outpatient
616 care centers, emergency departments) located in geographically diverse areas of
617 the city. We also provide reference laboratory services for other healthcare
618 entities in the Houston area. Together, our facilities serve patients of diverse
619 ethnicities and socioeconomic status. Thus, the data presented here likely reflect
620 a broad overview of virus diversity causing COVID-19 infections throughout
621 metropolitan Houston. We previously exploited these features to study influenza
622 and *Klebsiella pneumoniae* dissemination in metropolitan Houston (89, 90). We
623 acknowledge that every “twig” of the SARS-CoV-2 evolutionary tree in Houston is
624 not represented in these data. The samples studied are not comprehensive for
625 the entire metropolitan region. For example, it is possible that our strain samples
626 are not fully representative of individuals who are indigent, homeless, or of very
627 low socioeconomic groups. In addition, although the strain sample size is
628 relatively large compared to other studies, the sample represents only about 10%
629 of all COVID-19 cases in metropolitan Houston documented in the study period.
630 In addition, some patient samples contain relatively small amounts of virus
631 nucleic acid and do not yield adequate sequence data for high-quality genome

632 analysis. Thus, our data likely underestimate the extent of genome diversity
633 present among SARS-CoV-2 causing COVID-19 and will not identify all amino
634 acid replacements in the virus in this geographic region. It will be important to
635 sequence and analyze the genomes of additional SARS-CoV-2 strains causing
636 COVID-19 cases in the ongoing second massive disease wave in metropolitan
637 Houston, and these studies are underway. Data of this type will be especially
638 important to have if a third and subsequent waves were to occur in metropolitan
639 Houston, as it could provide insight into molecular and epidemiologic events
640 contributing to them.

641 The genomes reported here are an important data resource that will
642 underpin our ongoing study of SARS-CoV-2 molecular evolution, dissemination,
643 and medical features of COVID-19 in Houston. As of August 19, 2020, there
644 were 135,866 reported cases of COVID-19 in metropolitan Houston, and the
645 number of cases is increasing daily. Although the full array of factors contributing
646 to the massive second wave in Houston is not known, it is possible that the
647 potential for increased transmissibility of SARS-CoV-2 with the Gly614 may have
648 played a role, as well as changes in behavior associated with the Memorial Day
649 and July 4th holidays, and relaxation of some of the social constraints imposed
650 during the first wave. The availability of extensive virus genome data dating from
651 the earliest reported cases of COVID-19 in metropolitan Houston, coupled with
652 the database we have now constructed, may provide critical insights into the
653 origin of new infection spikes and waves occurring as public health constraints
654 are further relaxed, schools and colleges re-open, holidays occur, commercial air

655 travel increases, and individuals change their behavior because of COVID-19
656 “fatigue.” The genome data will also be useful in assessing ongoing molecular
657 evolution in spike and other proteins as baseline herd immunity is generated,
658 either by natural exposure to SARS-CoV-2 or by vaccination. The signal of
659 potential selection contributing to some spike protein diversity and identification
660 of naturally occurring mutant RBD variants with altered serologic recognition
661 warrant close attention and expanded study.

662

663 **MATERIALS AND METHODS**

664 **Patient specimens.** All specimens were obtained from individuals who
665 were registered patients at Houston Methodist hospitals, associated facilities
666 (e.g., urgent care centers), or institutions in the greater Houston metropolitan
667 region that use our laboratory services. Virtually all individuals met the criteria
668 specified by the Centers for Disease Control and Prevention to be classified as a
669 person under investigation.

670

671 **SARS-CoV-2 molecular diagnostic testing.** Specimens obtained from
672 symptomatic patients with a high degree of suspicion for COVID-19 disease were
673 tested in the Molecular Diagnostics Laboratory at Houston Methodist Hospital
674 using an assay granted Emergency Use Authorization (EUA) from the FDA
675 ([https://www.fda.gov/medical-devices/emergency-situations-medical-](https://www.fda.gov/medical-devices/emergency-situations-medical-devices/faqs-diagnostic-testing-sars-cov-2#offeringtests)
676 [devices/faqs-diagnostic-testing-sars-cov-2#offeringtests](https://www.fda.gov/medical-devices/emergency-situations-medical-devices/faqs-diagnostic-testing-sars-cov-2#offeringtests)). Multiple testing
677 platforms were used, including an assay that follows the protocol published by

678 the WHO ([https://www.who.int/docs/default-source/coronaviruse/protocol-v2-](https://www.who.int/docs/default-source/coronaviruse/protocol-v2-1.pdf)
679 [1.pdf](https://www.who.int/docs/default-source/coronaviruse/protocol-v2-1.pdf)) using the EZ1 virus extraction kit and EZ1 Advanced XL instrument or
680 QIASymphony DSP Virus kit and QIASymphony instrument for nucleic acid
681 extraction and ABI 7500 Fast Dx instrument with 7500 SDS software for reverse
682 transcription RT-PCR, the COVID-19 test using BioFire Film Array 2.0
683 instruments, the Xpert Xpress SARS-CoV-2 test using Cepheid GeneXpert
684 Infinity or Cepheid GeneXpert Xpress IV instruments, the SARS-CoV-2 Assay
685 using the Hologic Panther instrument, and the Aptima SARS-CoV-2 Assay using
686 the Hologic Panther Fusion system. All assays were performed according to the
687 manufacturer's instructions. Testing was performed on material obtained from
688 nasopharyngeal or oropharyngeal swabs immersed in universal transport media
689 (UTM), bronchoalveolar lavage fluid, or sputum treated with dithiothreitol (DTT).
690 To standardize specimen collection, an instructional video was created for
691 Houston Methodist healthcare workers
692 (<https://vimeo.com/396996468/2228335d56>).

693

694 **Epidemiologic curve.** The number of confirmed COVID-19 positive cases
695 was obtained from USAFacts.org ([https://usafacts.org/visualizations/coronavirus-](https://usafacts.org/visualizations/coronavirus-covid-19-spread-map/)
696 [covid-19-spread-map/](https://usafacts.org/visualizations/coronavirus-covid-19-spread-map/)) for Austin, Brazoria, Chambers, Fort Bend, Galveston,
697 Harris, Liberty, Montgomery, and Waller counties. Positive cases for Houston
698 Methodist Hospital patients were obtained from our Laboratory Information
699 System and plotted using the documented collection time.

700

701 **SARS-CoV-2 genome sequencing.** Libraries for whole virus genome
702 sequencing were prepared according to version 1 or version 3 of the ARTIC
703 nCoV-2019 sequencing protocol (<https://artic.network/ncov-2019>). Long reads
704 were generated with the LSK-109 sequencing kit, 24 native barcodes (NBD104
705 and NBD114 kits), and a GridION instrument (Oxford Nanopore). Short reads
706 were generated with the NexteraXT kit and NextSeq 550 instrument (Illumina).

707

708 **SARS-CoV-2 genome sequence analysis.** Consensus virus genome
709 sequences from the Houston area isolates were generated using the ARTIC
710 nCoV-2019 bioinformatics pipeline. Publicly available genomes and metadata
711 were acquired through GISAID on August 19, 2020. GISAID sequences
712 containing greater than 1% N characters, and Houston sequences with greater
713 than 5% N characters were removed from consideration. Identical GISAID
714 sequences originating from the same geographic location with the same
715 collection date were also removed from consideration to reduce redundancy.
716 Nucleotide sequence alignments for the combined Houston and GISAID strains
717 were generated using MAFFT version 7.130b with default parameters (91).
718 Sequences were manually curated in JalView (92) to trim the ends and to
719 remove sequences containing spurious inserts. Phylogenetic trees were
720 generated using FastTree with the generalized time-reversible model for
721 nucleotide sequences (93). CLC Genomics Workbench (QIAGEN) was used to
722 generate the phylogenetic tree figures.

723

724 **Geospatial mapping.** The home address zip code for all SARS-CoV-2
725 positive patients was used to generate the geospatial maps. To examine
726 geographic relatedness among genetically similar isolates, geospatial maps were
727 filtered to isolates containing specific amino acid changes.

728

729 **Time series.** Geospatial data were filtered into wave 1 (3/5/2020-
730 5/11/2020) and wave 2 (5/12/2020-7/7/2020) time intervals to illustrate the
731 spread of confirmed SARS-CoV-2 positive patients identified over time.

732

733 **Machine learning.** Virus genome alignments and patient metadata were
734 used to build models to predict patient metadata and outcomes using both
735 classification models and regression. Metadata considered for prediction in the
736 classification models included age, ABO and Rh blood type, ethnic group,
737 ethnicity, sex, ICU admission, IMU admission, supplemental oxygen use, and
738 ventilator use. Metadata considered for prediction in regression analysis included
739 ICU length of stay, IMU length of stay, total length of stay, supplemental oxygen
740 use, and ventilator use. Because sex, blood type, Rh factor, age, age decade,
741 ethnicity, and ethnic group are features in the patient features and combined
742 feature sets, models were not trained for these labels using patient and
743 combined feature sets. Additionally, age, length of stay, IMU length of stay, ICU
744 length of stay, mechanical ventilation days, and supplemental oxygen days were
745 treated as regression problems and XGBoost regressors were built while the rest
746 were treated as classification problems and XGBoost classifiers were built.

747 Three types of features were considered for training the XGBoost
748 classifiers: alignment features, patient features, and the combination of alignment
749 and patient features. Alignment features were generated from the consensus
750 genome alignment such that columns containing ambiguous nucleotide bases
751 were removed to ensure the models did not learn patterns from areas of low
752 coverage. These alignments were then one-hot encoded to form the alignment
753 features. Patient metadata values were one-hot encoded with the exception of
754 age, which remained as a raw integer value, to create the patient features.
755 These metadata values consisted of age, ABO, Rh blood type, ethnic group,
756 ethnicity, and sex. All three types of feature sets were used to train models that
757 predict ICU length of stay, IMU length of stay, overall length of stay, days of
758 supplemental oxygen therapy, and days of ventilator usage while only alignment
759 features were used to train models that predict age, ABO, Rh blood type, ethnic
760 group, ethnicity, and sex.

761 A ten-fold cross validation was used to train XGBoost models (94) as
762 described previously (95, 96). Depths of 4, 8, 16, 32, and 64 were used to tune
763 the models, but accuracies plateaued after a depth of 16. SciKit-Learn's (97)
764 classification report and r2 score were then used to assess overall accuracy of
765 the classification and regression models, respectively.

766

767 **Patient metadata correlations.** We encoded values into multiple columns
768 for each metadata field. For example, the ABO column was divided into four
769 columns for A, B, AB, and O blood type. Those columns were encoded with a 1

770 for the patients' ABO type, with all other columns encoded with 0. This was
771 repeated for all non-outcome metadata fields. Age, however, was not re-
772 encoded, as the raw integer values were used. Each column was then correlated
773 to the various outcome values for each patient (deceased, ICU length, IMU
774 length, length of stay, supplemental oxygen length, and ventilator length) to
775 obtain a Pearson coefficient correlation value for each metadata label and
776 outcome.

777

778 **Analysis of the *nsp12* polymerase and S protein genes.** The *nsp12*
779 virus polymerase and S protein genes were analyzed by plotting SNP density in
780 the consensus alignment using Python (Python v3.4.3, Biopython Package
781 v1.72). The frequency of SNPs in the Houston isolates was assessed, along with
782 amino acid changes for nonsynonymous SNPs.

783

784 **Cycle threshold (Ct) comparison of SARS-CoV-2 strains with either**
785 **Asp614 or Gly614 amino acid replacements in the spike protein.** The cycle
786 threshold (Ct) for every sequenced strain that was detected from a patient
787 specimen using the SARS-CoV-2 Assay on the Hologic Panther instrument was
788 retrieved from the Houston Methodist Hospital Laboratory Information System.
789 Statistical significance between the mean Ct value for strains with an aspartate
790 ($n=102$) or glycine ($n=812$) amino acid at position 614 of the spike protein was
791 determined with the Mann-Whitney test (GraphPad PRISM 8).

792

793 **Creation and characterization of spike protein RBD variants.** Spike
794 RBD variants were cloned into the spike-6P (HexaPro; F817P, A892P, A899P,
795 A942P, K986P, V987P) base construct that also includes the D614G substitution
796 (pIF638). Briefly, a segment of the gene encoding the RBD was excised with
797 EcoRI and NheI, mutagenized by PCR, and assembled with a HiFi DNA
798 Assembly Cloning Kit (NEB).

799 FreeStyle 293-F cells (Thermo Fisher Scientific) were cultured and
800 maintained in a humidified atmosphere of 37°C and 8% CO₂ while shaking at
801 110-125rpm. Cells were transfected with plasmids encoding spike protein
802 variants using polyethylenimine. Three hours post-transfection, 5µM kifunensine
803 was added to each culture. Cells were harvested four days after transfection and
804 the protein containing supernatant was separated from the cells by two
805 centrifugation steps: 10 min at 500rcf and 20 min at 10,000rcf. Supernatants
806 were kept at 4°C throughout. Clarified supernatant was loaded on a Poly-Prep
807 chromatography column (Bio-Rad) containing Strep-Tactin Superflow resin (IBA),
808 washed with five column volumes (CV) of wash buffer (100mM Tris-HCl pH 8.0,
809 150mM NaCl; 1mM EDTA), and eluted with four CV of elution buffer (100mM
810 Tris-HCl pH 8.0, 150mM NaCl, 1mM EDTA, 2.5mM d-Desthiobiotin). The eluate
811 was spin-concentrated (Amicon Ultra-15) to 600µL and further purified via size-
812 exclusion chromatography (SEC) using a Superose 6 Increase 10/300 column
813 (G.E.) in SEC buffer (2mM Tris pH 8.0, 200mM NaCl and 0.02% NaN₃). Proteins
814 were concentrated to 300µL and stored in SEC buffer.

815 The RBD spike mutants chosen for analysis were all RBD amino acid
816 mutants identified by our genome sequencing study as of June 15, 2020. We
817 note that the exact boundaries of the RBD domain varies depending on the paper
818 used as reference. We used the boundaries demarcated in Figure 1A of Cai et al.
819 Science paper 21 July) (98) that have K528R located at the RBD-CTD1 interface.

820

821 **Differential scanning fluorimetry.** Recombinant spike proteins were
822 diluted to a final concentration of 0.05mg/mL with 5X SYPRO orange (Sigma) in
823 a 96-well qPCR plate. Continuous fluorescence measurements ($\lambda_{ex}=465\text{nm}$,
824 $\lambda_{em}=580\text{nm}$) were collected with a Roche LightCycler 480 II. The temperature
825 was increased from 22°C to 95°C at a rate of 4.4°C/min. We report the first
826 melting transition.

827

828 **Enzyme-linked immunosorbent assays.** ELISAs were performed to
829 characterize binding of S6P, S6P D614G, and S6P D614G-RBD variants to
830 human ACE2 and the RBD-binding monoclonal antibody CR3022. The ACE2-
831 hFc chimera was obtained from GenScript (Z03484), and the CR3022 antibody
832 was purchased from Abcam (Ab273073). Corning 96-well high-binding plates
833 (CLS9018BC) were coated with spike variants at 2 $\mu\text{g/mL}$ overnight at 4°C. After
834 washing four times with phosphate buffered saline + 0.1% Tween20 (PBST;
835 300 μL /well), plates were blocked with PBS+2% milk (PBSM) for 2 h at room
836 temperature and again washed four times with PBST. These were serially diluted
837 in PBSM 1:3 seven times in triplicate. After 1 h incubation at room temperature,

838 plates were washed four times in PBST, labeled with 50 μ L mouse anti-human
839 IgG1 Fc-HRP (SouthernBlots, 9054-05) for 45 min in PBSM, and washed again
840 in PBST before addition of 50 μ L 1-step Ultra TMB-ELISA substrate (Thermo
841 Scientific, 34028). Reactions were developed for 15 min and stopped by addition
842 of 50 μ L 4M H₂SO₄. Absorbance intensity (450nm) was normalized within a plate
843 and EC₅₀ values were calculated through 4-parameter logistic curve (4PL)
844 analysis using GraphPad PRISM 8.4.3.

845

846 **ACKNOWLEDGMENTS**

847 We thank Dr. Steven Hinrichs and colleagues at the Nebraska Public Health
848 Laboratory, and Dr. David Persse and colleagues at the Houston Health
849 Department for providing samples used to validate our initial SARS-CoV-2
850 molecular assay. We thank Drs. Jessica Thomas and Zejuan Li, Erika Walker,
851 Concepcion C. Cantu, the very talented and dedicated molecular technologists,
852 and the many labor pool volunteers in the Molecular Diagnostics Laboratory for
853 their dedication to patient care. We also thank Brandi Robinson, Harrold Cano,
854 Cory Romero, Brooke Burns, and Hayder Mahmood for technical assistance. We
855 are indebted to Drs. Marc Boom and Dirk Sostman for their support, and to many
856 very generous Houston philanthropists for their tremendous support of this
857 ongoing project, including but not limited to anonymous, Ann and John Bookout
858 III, Carolyn and John Bookout, Ting Tsung and Wei Fong Chao Foundation, Ann
859 and Leslie Doggett, Freeport LNG, the Hearst Foundations, Jerold B. Katz
860 Foundation, C. James and Carole Walter Looke, Diane and David Modesett, the

861 Sherman Foundation, and Paula and Joseph C. “Rusty” Walter III. We gratefully
862 acknowledge the originating and submitting laboratories of the SARS-CoV-2
863 genome sequences from GISAID’s EpiFlu™ Database used in some of the work
864 presented here. We also thank many colleagues for critical reading of the
865 manuscript and suggesting improvements, and Sasha Pejerrey, Adrienne
866 Winston, Heather McConnell, and Kathryn Stockbauer for editorial contributions.
867 We are especially indebted to Drs. Nancy Jenkins and Neal Copeland for their
868 scholarly suggestions to improve an early version of the manuscript.

869

870 **Author contributions:** J.M.M. conceptualized and designed the project; S.W.L,
871 R.J.O., P.A.C., D.W.B., J.J.D., M.S., M.N., M.O.S., C.C.C., P.Y., L.P., S.S., H.-C.
872 K., H.H., G.E., H.A.T.N., J.H.L., M.K., J.G., D.B., J.G., J.S.M., C.-W.C., K.J., and
873 I.F. performed research. All authors contributed to writing the manuscript.

874 Data and material availability: The spike-6P (“HexaPro”) plasmid is available from
875 Addgene (ID: 154754) or from I.J.F. under a material transfer agreement with
876 The University of Texas at Austin. Additional plasmids are available upon request
877 from I.J.F.

878

879 This study was supported by the Fondren Foundation, Houston Methodist
880 Hospital and Research Institute (to J.M.M.), NIH grant AI127521 (to J.S.M.), NIH
881 grants GM120554 and GM124141 to I.J.F., the Welch Foundation (F-1808 to
882 I.J.F.), and the National Science Foundation (1453358 to I.J.F.). I.J.F. is a CPRIT
883 Scholar in Cancer Research. J.J.D., M.S., and M.N. are supported by the NIAID

- 884 Bacterial and Viral Bioinformatics resource center award (contract number
885 75N93019C00076). J.J.D. and M.N. are also funded by the United States
886 Defense Advanced Research Projects Agency Award iSENTRY Friend or Foe
887 program award (contract number HR0011937807).

1330

1331 **FIG 1** (A) Confirmed COVID-19 cases in the Greater Houston Metropolitan region.
1332 Cumulative number of COVID-19 patients over time through July 7, 2020. Counties
1333 include Austin, Brazoria, Chambers, Fort Bend, Galveston, Harris, Liberty, Montgomery,
1334 and Waller. The shaded area represents the time period during which virus genomes
1335 characterized in this study were recovered from COVID-19 patients. The red line
1336 represents the number of COVID-19 patients diagnosed in the Houston Methodist
1337 Hospital Molecular Diagnostic Laboratory. (B) Distribution of strains with either the
1338 Asp614 or Gly614 amino acid variant in spike protein among the two waves of COVID-
1339 19 patients diagnosed in the Houston Methodist Hospital Molecular Diagnostic
1340 Laboratory. The large inset shows major clade frequency for the time frame studied.
1341

1342

1343 **FIG 2** Sequential time-series heatmaps for all COVID-19 Houston Methodist patients
1344 during the study period. Geospatial distribution of COVID-19 patients is based on zip
1345 code. Panel A (left) shows geospatial distribution of sequenced SARS-CoV-2 strains in
1346 wave 1 and panel B (right) shows wave 2 distribution. The collection dates are shown at
1347 the bottom of each panel. The insets refer to City numbers of strains in the color spectrum
1348 used. Note difference in numbers of strains used in panel A and panel B insets.

1349

1350

1351 **FIG 3** Location of amino acid replacements in RNA-dependent RNA polymerase
1352 (RdRp/Nsp12) among the 5,085 genomes of SARS-CoV-2 sequenced. The various
1353 RdRp domains are color-coded. The numbers refer to amino acid site. Note that several
1354 amino acid sites have multiple variants identified.

1355

1356

1357 **FIG 4** Amino acid changes identified in Nsp12 (RdRp) in this study that may influence
1358 interaction with remdesivir. The schematic at the top shows the domain architecture of
1359 Nsp12. (Left) Ribbon representation of the crystal structure of Nsp12-remdesivir
1360 monophosphate-RNA complex (PDB code: 7BV2). The structure in the right panel
1361 shows a magnified view of the boxed area in the left panel. The Nsp12 domains are
1362 colored as in the schematic at the top. The catalytic site in Nsp12 is marked by a black
1363 circle in the right panel. The side chains of amino acids comprising the catalytic site of
1364 RdRp (Ser758, Asp759, and Asp760) are shown as balls and stick and colored yellow.
1365 The nucleotide binding site is boxed in the right panel. The side chains of amino acids
1366 participating in nucleotide binding (Lys544, Arg552, and Arg554) are shown as balls and
1367 sticks and colored light blue. Remdesivir molecule incorporated into the nascent RNA is
1368 shown as balls and sticks and colored light pink. The RNA is shown as a blue cartoon
1369 and bases are shown as sticks. The positions of C α atoms of amino acids identified in

1370 this study are shown as red and green spheres and labeled. The amino acids that are
1371 shown as red spheres are located above the nucleotide binding site, whereas Cys812
1372 located at the catalytic site is shown as a green sphere. The side chain of active site
1373 residue Ser758 is shown as ball and sticks and colored yellow. The location of C α atoms
1374 of remdesivir resistance conferring amino acid Val556 is shown as blue sphere and
1375 labeled.
1376

It is made available under a [CC-BY-NC-ND 4.0 International license](https://creativecommons.org/licenses/by-nc-nd/4.0/).

1377

1378 **FIG 5** Location of amino acid replacements in spike protein among the 5,085 genomes
 1379 of SARS-CoV-2 sequenced. The various spike protein domains are color-coded. The
 1380 numbers refer to amino acid site. Note that many amino acid sites have multiple variants
 1381 identified.

1382

1383

1384 **FIG 6** Location of amino acid substitutions mapped on the SARS-CoV-2 spike protein.

1385 Model of the SARS-CoV-2 spike protein with one protomer shown as ribbons and the

1386 other two protomers shown as a molecular surface. The C α atom of residues found to be

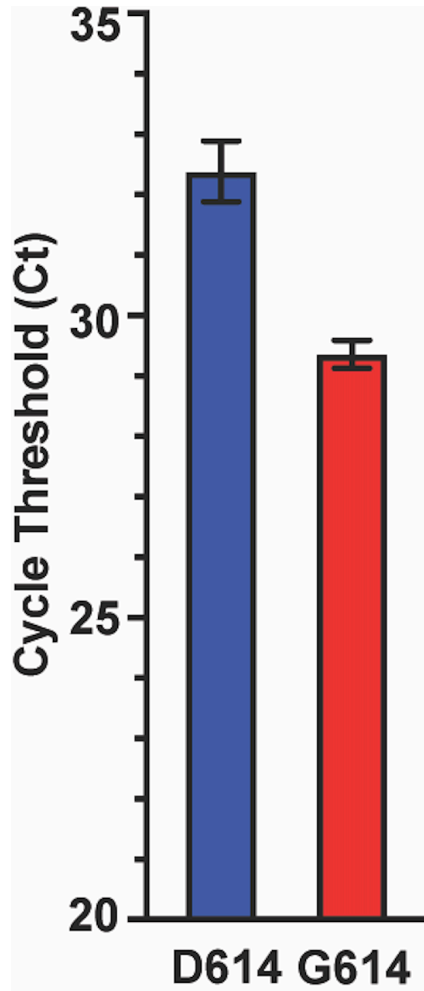

1387 substituted in one or more virus isolates identified in this study is shown as a sphere on

1388 the ribbon representation. Residues found to be substituted in 1–9 isolates are colored

1389 tan, 10–99 isolates yellow, 100–999 isolates colored red (H49Y and F1052L), and >1000

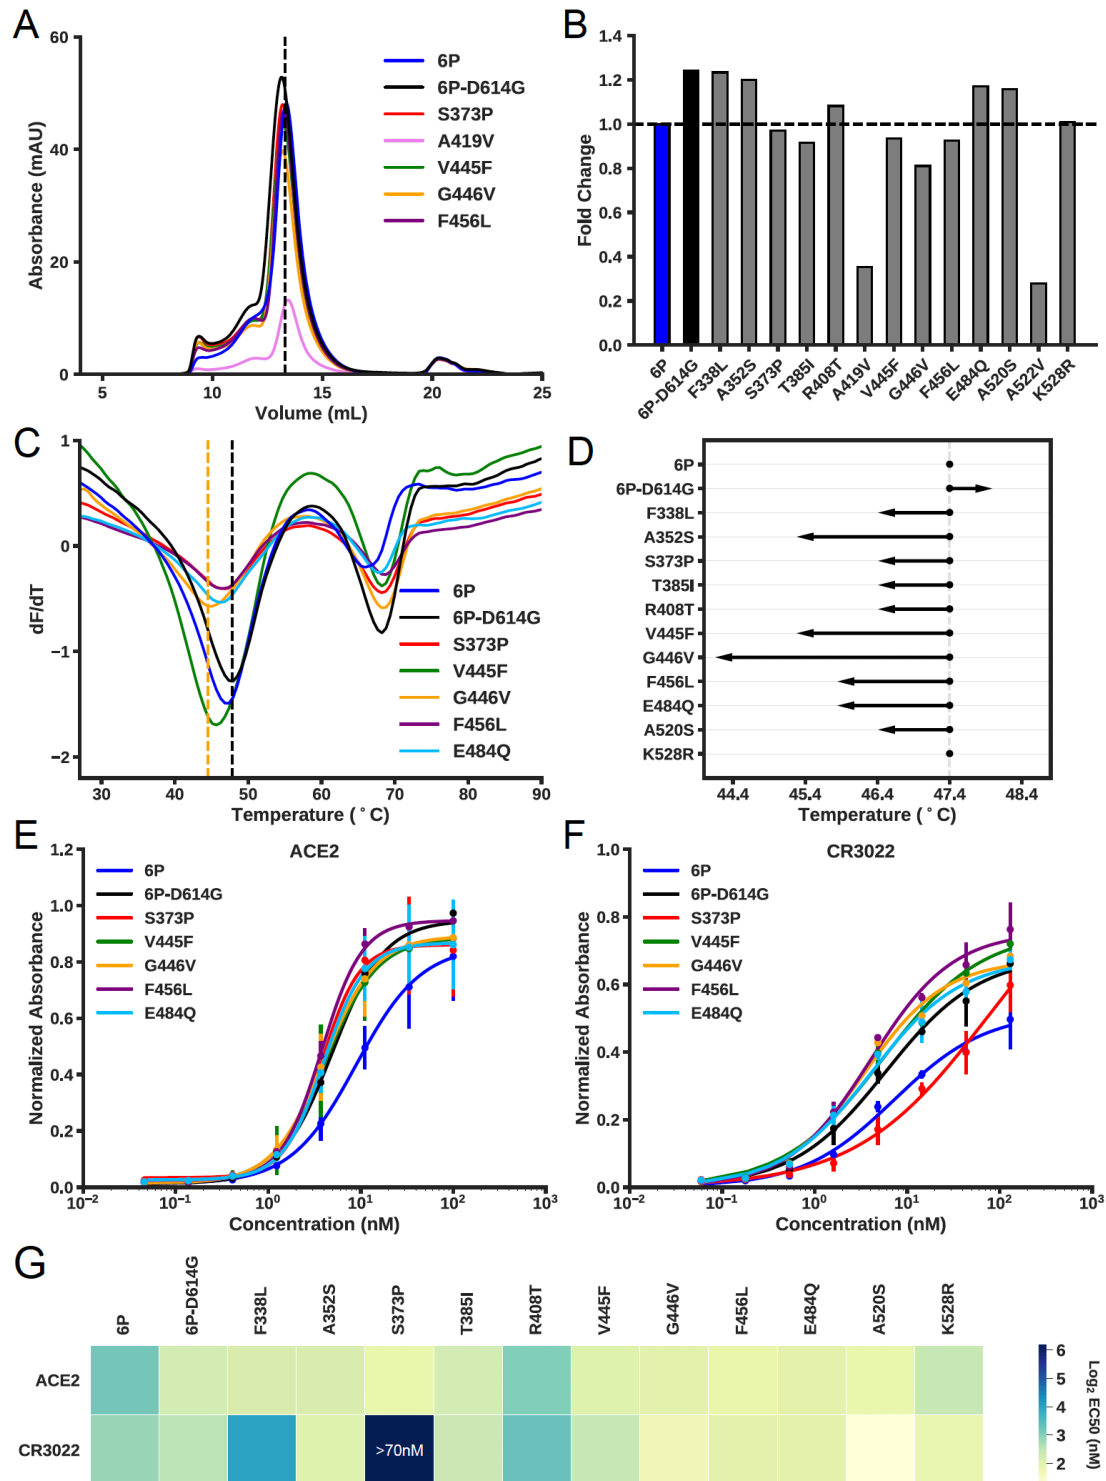

1390 isolates purple (D614G). The surface of the aminoterminal domain (NTD) that is distal to

1391 the trimeric axis has a high density of substituted residues. RBD, receptor binding
1392 domain.

1393

1394 **FIG 7** Cycle threshold (Ct) for every SARS-CoV-2 patient sample tested using the
1395 Hologic Panther assay. Data are presented as mean +/- standard error of the mean for
1396 strains with an aspartate (D614, $n=102$ strains, blue) or glycine (G614, $n=812$ strains,
1397 red) at amino acid 614 of the spike protein. Mann-Whitney test, $*P<0.0001$.

1398

1399 **FIG 8** Biochemical characterization of spike RBD variants. (A) Size-exclusion
 1400 chromatography (SEC) traces of the indicated spike-RBD variants. Dashed line indicates
 1401 the elution peak of spike-6P. (B) The relative expression of all RBD variants as

1402 determined by the area under the SEC traces. All expression levels are normalized
1403 relative to spike-6P. (C) Thermostability analysis of RBD variants by differential scanning
1404 fluorimetry. Each sample had three replicates and only mean values were plotted. Black
1405 vertical dashed line indicates the first melting temperature of 6P-D614G and orange
1406 vertical dashed line indicates the first melting temperature of the least stable variant
1407 (spike-G446V). (D) First apparent melting temperature of all RBD variants. (E) ELISA-
1408 based binding affinities for ACE2 and (F) the neutralizing antibody CR3022 to the
1409 indicated RBD variants. (G) Summary of EC50s for all measured RBD variants.
1410
1411

1412 **Table 1.** Nonsynonymous SNPs of SARS-CoV-2 *nsp12*.

1416

1417 The domain region of RBD is based on structural information found in Cai et al.
1418 2020 (98).

1419

1420

1421 Forty-nine of these amino acid replacements (V11A, T51A, W64C, I119T,
1422 E156Q, S205A, D228G, L229W, P230T, N234D, I235T, T274A, A288V, E324Q,
