## Abstract

21 Understanding the factors that mediate overdispersion in SARS-CoV-2 transmissibility is crucial  
22 towards mitigating the COVID-19 pandemic. Using a systematically developed dataset, we  
23 meta-analyze respiratory viral loads (rVLs) of SARS-CoV-2, SARS-CoV-1 and influenza  
24 A(H1N1)pdm09 from 15 countries and model infectiousness by shedding viable virus via  
25 droplets and aerosols. Our results indicate heterogeneity in rVL as an intrinsic virological factor  
26 facilitating greater overdispersion in the COVID-19 pandemic than in the 2009 H1N1 pandemic.  
27 For COVID-19, case heterogeneity remains broad throughout the infectious period, including for  
28 pediatric and asymptomatic infections. Many cases inherently present minimal transmission risk,  
29 whereas highly infectious individuals shed tens to thousands of SARS-CoV-2 virions/min via  
30 droplets and aerosols while breathing, talking and singing. Coughing increases the  
31 contagiousness, especially in close contact, of symptomatic cases relative to asymptomatic ones.  
32 Our findings show how individual case variations influence SARS-CoV-2 transmissibility and  
33 present considerations for disease control.

34

35 **One Sentence Summary:** Intrinsic case variation in respiratory viral load facilitates broad  
36 overdispersion in SARS-CoV-2 transmissibility.

37

## Main Text

38

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has spread globally, causing the coronavirus disease 2019 (COVID-19) pandemic with more than 50.9 million infections and 1.2 million deaths (as of 10 November 2020) (1). For respiratory virus transmission, airway epithelial cells shed virions to the extracellular fluid before atomization (from breathing, talking, singing, coughing and aerosol-generating procedures) partitions them into a polydisperse mixture of particles that are expelled to the ambient environment. Aerosols ( $\leq 100 \mu\text{m}$ ) can be inhaled nasally, whereas droplets ( $> 100 \mu\text{m}$ ) tend to be excluded (2, 3). For direct transmission, droplets must be sprayed ballistically onto susceptible tissue (4). Hence, droplets predominantly deposit on nearby surfaces, potentiating indirect transmission. Aerosols can be further categorized based on typical travel characteristics: short-range aerosols (50-100  $\mu\text{m}$ ) tend to settle within 2 m; long-range ones (10-50  $\mu\text{m}$ ) often travel beyond 2 m based on emission force; and buoyant aerosols ( $\leq 10 \mu\text{m}$ ) remain suspended and travel based on airflow profiles for minutes to many hours (4, 5). Although proximity has been associated with infection risk for COVID-19 (6), studies have also suggested that long-range airborne transmission occurs conditionally (7-9).

52

While the basic reproductive number has been estimated to be 2.0-3.6 (10, 11), transmissibility of SARS-CoV-2 is highly overdispersed (dispersion parameter  $k$ , 0.10-0.58), with numerous instances of superspreading (7-9) and few cases (10-20%) causing many secondary infections (80%) (12-14). Similarly, few cases drive the transmission of SARS-CoV-1 ( $k$ , 0.16-0.17) (15), whereas influenza A(H1N1)pdm09 transmits more homogeneously ( $k$ , 7.4-14.4) (16, 17), despite both viruses spreading by contact, droplets and aerosols (18, 19). Although understanding the determinants of overdispersion is crucial towards characterizing transmissibility and developing effective strategies to limit infection (20), mechanistic

60 associations for  $k$  remain unclear. As an empirical estimate,  $k$  depends on myriad extrinsic  
61 (behavioral, environmental and invention) and host factors. Nonetheless,  $k$  remains similar across  
62 distinct outbreaks of a virus (15), suggesting that intrinsic virological factors mediate  
63 overdispersion for emerging infections.

64 Here, we investigated how intrinsic case variation in rVL facilitates overdispersion in  
65 SARS-CoV-2 transmissibility. By systematic review, we developed a comprehensive dataset of  
66 rVLs from cases of COVID-19, SARS and A(H1N1)pdm09. Using comparative meta-analyses,  
67 we found that heterogeneity in rVL was associated with overdispersion among these emerging  
68 infections. To assess potential sources of case heterogeneity, we analyzed SARS-CoV-2 rVLs  
69 across age and symptomatology subgroups as well as disease course. To interpret the influence  
70 of heterogeneity in rVL on individual infectiousness, we modelled likelihoods of shedding viable  
71 virus via respiratory droplets and aerosols.

72

### 73 Systematic review

74 We conducted a systematic review on virus quantitation in respiratory specimens taken during  
75 the infectious periods of SARS-CoV-2 (-3 to 10 days from symptom onset [DFSO]) (21-23),  
76 SARS-CoV-1 (0-20 DFSO) (24) and A(H1N1)pdm09 (-2 to 9 DFSO) (25) (Methods). The  
77 systematic search (Tables S1 to S5) identified 4,274 results. After screening and full-text review,  
78 63 studies met the inclusion criteria and contributed to the systematic dataset (Fig. 1) ( $N = 9,616$   
79 total specimens), which included adult ( $N = 5,030$ ) and pediatric ( $N = 1,594$ ) cases from 15  
80 countries and specimen measurements for asymptomatic ( $N = 2,387$ ), presymptomatic ( $N = 28$ )  
81 and symptomatic ( $N = 7,146$ ) infections. According to a hybrid Joanna Briggs Institute critical  
82 appraisal checklist, risk of bias was low for most contributing studies (Table S6).

83

84 **Association of overdispersion with heterogeneity in rVL**

85 We hypothesized that individual case variation in rVL facilitates the distinctions in  $k$  among  
86 COVID-19, SARS and A(H1N1)pdm09. For each study in the systematic dataset, we used  
87 specimen measurements (viral RNA concentration in a respiratory specimen) to estimate rVLs  
88 (viral RNA concentration in the respiratory tract) (Methods). To investigate the relationship  
89 between  $k$  and heterogeneity in rVL, we performed a meta-regression using each contributing  
90 study (fig. S1), which showed a weak, negative association between the two variables (meta-  
91 regression slope  $t$ -test:  $P = 0.040$ , Pearson's  $r = -0.26$ ).

92 Using contributing studies with low risk of bias, meta-regression (Fig. 2) showed a  
93 strong, negative association between  $k$  and heterogeneity in rVL (meta-regression slope  $t$ -test:  $P$   
94  $< 10^{-8}$ , Pearson's  $r = -0.73$ ). In this case, each unit increase ( $1 \log_{10}$  copies/ml) in the SD of rVL  
95 decreased  $\log(k)$  by a factor of -1.41 (95% confidence interval [CI]: -1.80 to -1.03), suggesting  
96 that broader heterogeneity in rVL facilitates greater overdispersion in the transmissibility of  
97 SARS-CoV-2 than of A(H1N1)pmd09. To investigate mechanistic aspects of this association, we  
98 conducted a series of analyses on rVL and then modelled the influence of heterogeneity in rVL  
99 on individual infectiousness.

100

101 **Meta-analysis and subgroup analyses of rVL**

102 We first compared rVLs among the emerging infections. We performed a random-effects meta-  
103 analysis (fig. S2), which assessed the expected rVL when encountering a COVID-19, SARS or  
104 A(H1N1)pdm09 case during the infectious period. This showed that the expected rVL of SARS-  
105 CoV-2 was not different from that of SARS-CoV-1 (one-sided Welch's  $t$ -test:  $P = 0.102$ ) but

106 lesser than that of A(H1N1)pdm09 ( $P = 0.044$ ). We also performed random-effects subgroup  
107 analyses for COVID-19 (Fig. 3), which showed that expected SARS-CoV-2 rVLs were similar  
108 between pediatric and adult cases ( $P = 0.409$ ) and comparable between  
109 symptomatic/presymptomatic and asymptomatic infections ( $P = 0.107$ ). Since these meta-  
110 analyses had significant between-study heterogeneity among the mean estimates (Cochran's  $Q$   
111 test:  $P < 0.001$  for each meta-analysis), we conducted risk-of-bias sensitivity analyses; meta-  
112 analyses of low-risk-of-bias studies continued to show significant heterogeneity (figs. S3 to S7).

113

#### 114 **Distributions of rVL**

115 We next analyzed rVL distributions. For all three viruses, rVLs best conformed to Weibull  
116 distributions (fig. S8), and we fitted the entirety of individual sample data for each virus in the  
117 systematic dataset (Fig. 4A and fig. S8N). While COVID-19 and SARS cases tended to shed  
118 lesser virus than those with A(H1N1)pdm09 (fig. S2), broad heterogeneity in SARS-CoV-2 and  
119 SARS-CoV-1 rVLs inverted this relationship for highly infectious individuals (Fig. 4A and fig.  
120 S9, A to C). At the 90<sup>th</sup> case percentile (cp) throughout the infectious period, the estimated rVL  
121 was 8.91 (95% CI: 8.83-9.00) log<sub>10</sub> copies/ml for SARS-CoV-2, whereas it was 8.62 (8.47-8.76)  
122 log<sub>10</sub> copies/ml for A(H1N1)pdm09 (Table S7). The standard deviation (SD) of the overall rVL  
123 distribution for SARS-CoV-2 was 2.04 log<sub>10</sub> copies/ml, while it was 1.45 log<sub>10</sub> copies/ml for  
124 A(H1N1)pdm09, showing that heterogeneity in rVL was indeed broader for SARS-CoV-2.

125 To assess potential sources of heterogeneity in SARS-CoV-2 rVL, we compared rVL  
126 distributions among COVID-19 subgroups. In addition to comparable mean estimates (Fig. 3),  
127 adult, pediatric, symptomatic/presymptomatic and asymptomatic COVID-19 cases showed  
128 similar rVL distributions (Fig. 4, B and C), with SDs of 2.04, 2.06, 2.01 and 2.02 log<sub>10</sub>

129 copies/ml, respectively. Thus, age and symptomatology minimally influenced case variation in  
130 SARS-CoV-2 rVL during the infectious period.

131

132 **SARS-CoV-2 kinetics during respiratory infection**

133 To analyze the influences of disease course, we delineated individual SARS-CoV-2 rVLs by  
134 DFSO and fitted the mean estimates to a mechanistic model for viral kinetics (Fig. 4D,  
135 Methods). The outputs indicated that, on average, each productively infected cell in the airway  
136 epithelium shed SARS-CoV-2 at 1.83 (95% CI: 0.69-2.97) copies/ml day<sup>-1</sup> and infected up to  
137 9.48 susceptible cells (Table S8). The turnover rate for infected epithelial cells was 0.55 (0.30-  
138 0.79) days<sup>-1</sup>, while the half-life of SARS-CoV-2 in the respiratory tract was 2.65 (1.39-28.2)  
139 hours. By extrapolating the model to an initial rVL of 0 log<sub>10</sub> copies/ml, the estimated incubation  
140 period was 5.09 days, which agrees with epidemiological findings (10). Conversely, the expected  
141 duration of shedding was 30.4 DFSO. Thus, SARS-CoV-2 rVL increased exponentially after  
142 infection, peaked around 1 DFSO along with the proportion of infected epithelial cells (fig. S10)  
143 and then diminished exponentially.

144 To evaluate case heterogeneity across the infectious period, we fitted distributions for  
145 each DFSO (Fig. 4E), which showed that high SARS-CoV-2 rVLs also increased from the  
146 presymptomatic period, peaked at 1 DFSO and then decreased towards the end of the first week  
147 of illness. For the 90<sup>th</sup> cp at 1 DFSO, the rVL was 9.83 (95% CI: 9.12-10.61) log<sub>10</sub> copies/ml, an  
148 order of magnitude greater than the overall 90<sup>th</sup>-cp estimate. High rVLs between 1-5 DFSO were  
149 elevated above the expected values from the overall rVL distribution (Table S7). At -1 DFSO,  
150 the 90<sup>th</sup>-cp rVL was 8.30 (6.88-10.02) log<sub>10</sub> copies/ml, while it was 7.96 (7.37-8.58) log<sub>10</sub>

151 copies/ml at 10 DFSO. Moreover, heterogeneity in rVL remained broad across the infectious  
152 period, with SDs of 1.85-2.46  $\log_{10}$  copies/ml between -1 to 10 DFSO (fig. S9, H to S).

153

154 **Likelihood that droplets and aerosols contain virions**

155 Towards analyzing the influence of heterogeneity in rVL on individual infectiousness, we first  
156 modelled the likelihood of respiratory particles containing viable SARS-CoV-2. Since rVL is an  
157 intensive quantity, the volume fraction of virions is low and viral partitioning coincides with  
158 atomization, we used Poisson statistics to model likelihood profiles. To calculate an unbiased  
159 estimator of partitioning (the expected number of viable copies per particle), our method  
160 multiplied rVL estimates with particle volumes during atomization and an assumed viability  
161 proportion of 0.1% in equilibrated particles (Methods).

162 When expelled by the mean COVID-19 case during the infectious period, respiratory  
163 particles showed low likelihoods of carrying viable SARS-CoV-2 (fig. S11B). Aerosols  
164 (equilibrium aerodynamic diameter [ $d_a$ ]  $\leq$  100  $\mu\text{m}$ ) were  $\leq$  0.69% (95% CI: 0.43-0.95%) likely to  
165 contain a virion. Droplets also had low likelihoods: at  $d_a$  = 330  $\mu\text{m}$ , they were 19.4% (18.5-  
166 20.3%), 2.42% (2.15-2.69%) and 0.20% (0.16-0.24%) likely to contain one, two or three virions,  
167 respectively.

168 COVID-19 cases with high rVLs, however, expelled particles with considerably greater  
169 likelihoods of carrying viable copies (Fig. 5, A and B, and fig. S11, D and E). For the 80<sup>th</sup> cp  
170 during the infectious period, aerosols ( $d_a \leq$  100  $\mu\text{m}$ ) were  $\leq$  36.6% (95% CI: 35.3-38.0%) likely  
171 to carry at least one SARS-CoV-2 virion. For the 90<sup>th</sup> cp, this likelihood was  $\leq$  96.7% (96.5-  
172 96.9%), with larger aerosols tending to contain multiple virions (fig. S11E). At 1 DFSO, these  
173 estimates were greatest, and  $\leq$  65.2% (56.1-74.3%) of buoyant aerosols ( $d_a \leq$  10  $\mu\text{m}$ ) contained at

174 least one viable copy of SARS-CoV-2 for the 98<sup>th</sup> cp. When expelled by high cps, droplets ( $d_a >$   
175 100  $\mu\text{m}$ ) tended to contain tens to thousands of SARS-CoV-2 virions (fig. S11E and Fig. 5B)

176  
177 **Shedding SARS-CoV-2 via respiratory droplets and aerosols**

178 Using the partitioning estimates in conjunction with published profiles of the particles expelled  
179 by respiratory activities (fig. S12), we next modelled the rates at which talking, singing,  
180 breathing and coughing shed viable SARS-CoV-2 across  $d_a$  (Fig. 5, C to F). Singing shed virions  
181 more rapidly than talking based on the increased emission of aerosols. Voice amplitude,  
182 however, had a significant effect on aerosol production, and talking loudly emitted aerosols at  
183 similar rates to singing (fig. S12E). Based on the generation of larger aerosols and droplets,  
184 talking and singing shed virions more rapidly than breathing (Fig. 5, C to E). Each cough shed  
185 similar quantities of virions as in a minute of talking (Fig. 5, C and F).

186 Each of these respiratory activities expelled aerosols at greater rates than droplets, but  
187 particle size correlated with the likelihood of containing virions. Talking, singing and coughing  
188 expelled virions at greater proportions via droplets (80.6-86.0%) than aerosols (14.0-19.4%)  
189 (Fig. 5G). Moreover, short-range aerosols predominantly mediated the virions (90.8-92.6%) shed  
190 via aerosols while talking normally and coughing. In comparison, while singing, talking loudly  
191 and breathing, buoyant (29.7-68.4%) and long-range (10.3-31.6%) aerosols carried a larger  
192 proportion of the virions shed via aerosols (Fig. 5G).

193  
194 **Influence of heterogeneity in rVL on individual infectiousness**

195 To interpret how heterogeneity in rVL influences individual infectiousness, we modelled total  
196 SARS-CoV-2 shedding rates (over all particle sizes) for each respiratory activity (Fig. 5H and

197 fig. S13). Between the 1<sup>st</sup> and the 99<sup>th</sup> cps, the estimates for a respiratory activity spanned  $\geq 8.55$   
198 orders of magnitude on each DFSO; cumulatively from -1 to 10 DFSO, they spanned 11.0 orders  
199 of magnitude. Hence, many COVID-19 cases inherently presented minimal transmission risk,  
200 whereas highly infectious individuals shed considerable quantities of SARS-CoV-2. For the 98<sup>th</sup>  
201 cp at 1 DFSO, singing expelled 350 (95% CI: 36.2-4,213) virions/min to the ambient  
202 environment, talking emitted 328 (33.9-3,945) virions/min, breathing exhaled 1.73 (0.18-20.7)  
203 virions/min and coughing discharged 279 (28.8-3,350) virions/cough; these estimates were  
204 approximately two orders of magnitude greater than those for the 86<sup>th</sup> cp. For the 98<sup>th</sup> cp at -1  
205 DFSO, singing shed 14.5 (0.15-4,515) virions/min and breathing exhaled  $7.13 \times 10^{-2}$  ( $7.20 \times 10^{-4}$ -  
206 22.2) virions/min. The estimates at 9-10 DFSO were similar to these presymptomatic ones (Fig.  
207 5H and fig. S13B). As indicated by comparable mean rVLs (Fig. 3) and heterogeneities in rVL  
208 (Fig. 4, B and C), adult, pediatric, symptomatic/presymptomatic and asymptomatic COVID-19  
209 subgroups presented similar distributions for shedding virions through these activities.

210 We also compared the influence of case variation on individual infectiousness between  
211 A(H1N1)pdm09 and COVID-19. Aerosol spread accounted for approximately half of  
212 A(H1N1)pdm09 transmission events (19), and the 50% human infectious dose for aerosolized  
213 influenza A virus is approximately 1-3 virions in the absence of neutralizing antibodies (26).  
214 Based on the model, 62.9% of A(H1N1)pdm09 cases were infectious (shed  $\geq 1$  virion) via  
215 aerosols within 24 h of talking loudly or singing (fig. S14A). The estimate was 58.6% within 24  
216 h of talking normally and 22.3% within 24 h of breathing. In comparison, 48.0% of COVID-19  
217 cases shed  $\geq 1$  virion via aerosols in 24 h of talking loudly or singing (fig. S14C). Notably, only  
218 61.4% of COVID-19 cases shed  $\geq 1$  virion via either droplets or aerosols in 24 h of talking loudly  
219 or singing (fig. S14D). While the human infectious dose of SARS-CoV-2 by any exposure route

220 remains unelucidated, it must be at least one viable copy. Thus, at least 38.6% of COVID-19  
221 cases were expected to present negligible risk to spread SARS-CoV-2 through either droplets or  
222 aerosols in 24 h. The proportion of inherently infectious cases further decreased as the infectious  
223 dose increased: 55.8, 42.5 and 25.0% of COVID-19 cases were expected to shed  $\geq 2$ ,  $\geq 10$  and  
224  $\geq 100$  virions, respectively, in 24 h of talking loudly or singing.

225 While these analyses indicated that a greater proportion of A(H1N1)pdm09 cases were  
226 inherently infectious, 18.8% of COVID-19 cases shed virions more rapidly than those infected  
227 with A(H1N1)pdm09 (Fig. 4A). At the 98<sup>th</sup> cp for A(H1N1)pdm09, singing expelled 4.38 (2.85-  
228 6.78) virions/min and breathing exhaled  $2.15 \times 10^{-2}$  ( $1.40 \times 10^{-2}$ - $3.34 \times 10^{-2}$ ) virions/min. Highly  
229 infectious COVID-19 cases expelled virions at rates that were up to 1-2 orders of magnitude  
230 greater than their A(H1N1)pdm09 counterparts (Fig. 5H and fig. S15).

231

## 232 Discussion

233 This study provided systematic analyses of several factors characterizing SARS-CoV-2  
234 transmissibility. First, we found that broader heterogeneity in rVL facilitates greater  
235 overdispersion for SARS-CoV-2 than A(H1N1)pdm09. Our results suggest that many COVID-  
236 19 cases infect no one (12-14) because they inherently present minimal transmission risk via  
237 droplets or aerosols, although behavioral and environmental factors can further abate risk.  
238 Meanwhile, highly infectious cases can shed tens to thousands of SARS-CoV-2 virions/min. The  
239 model estimates, when corrected to copies rather than virions, align with recent clinical findings  
240 for exhalation rates of SARS-CoV-2 (27). In comparison, a greater proportion of  
241 A(H1N1)pdm09 cases are infectious but shed virions at low rates, which concurs with more  
242 uniform transmission and few superspreading events observed during the 2009 H1N1 pandemic

243 (16, 17). Moreover, our analyses suggest that heterogeneity in rVL may be generally associated  
244 with overdispersion for viral respiratory infections. In this case, rVL distribution can serve as an  
245 early correlate for transmission patterns, including superspreading, during outbreaks of novel  
246 respiratory viruses, providing insight for disease control before large-scale epidemiological  
247 studies empirically characterize  $k$ . When transmission is highly overdispersed, targeted  
248 interventions may disproportionately mitigate infection (20), with models estimating that  
249 focusing half of control efforts on the most infectious 20% of cases outperforms random control  
250 policies threefold (15).

251 Second, we analyzed SARS-CoV-2 kinetics during respiratory infection. While  
252 heterogeneity remains broad throughout the infectious period, rVL tends to peak at 1 DFSO and  
253 be elevated for 1-5 DFSO, coinciding with the period of highest attack rates observed among  
254 close contacts (28). These results indicate that transmission risk tends to be greatest soon after  
255 illness rather than in the presymptomatic period, which concurs with large tracing studies (6.4-  
256 12.6% of secondary infections from presymptomatic transmission) (29, 30) rather than early  
257 temporal models (~44%) (23). Furthermore, our kinetic analysis suggests that, on average,  
258 SARS-CoV-2 reaches diagnostic concentrations 1.58-3.03 days after respiratory infection (-3.51  
259 to -2.06 DFSO), assuming assay detection limits of 1-3  $\log_{10}$  copies/ml, respectively, for  
260 nasopharyngeal swabs immersed in 1 ml of transport media.

261 Third, we assessed the relative infectiousness of COVID-19 subgroups. As a common  
262 symptom of COVID-19 (31), coughing sheds considerable numbers of virions via droplets and  
263 short-range aerosols. Thus, symptomatic infections tend to be more contagious than  
264 asymptomatic ones, providing one reason as to why asymptomatic cases transmit SARS-CoV-2  
265 at lower relative rates (32), especially in close contact (33), despite similar rVLs and increased

266 contact patterns. Accordingly, children (48-54% of symptomatic cases present with cough) (34,  
267 35) tend to be less contagious than adults (68-80%) (31, 35) based on tendencies of  
268 symptomatology rather than rVL. Conversely, coughing sheds few virions via smaller aerosols.  
269 Our analyses suggest that asymptomatic and symptomatic infections present comparable risks for  
270 airborne spread, as do adult and pediatric cases. While singing and talking loudly, highly  
271 infectious individuals shed tens to hundreds of SARS-CoV-2 virions/min via long-range and  
272 buoyant aerosols.

273 Our study has limitations. The systematic search found a limited number of studies  
274 reporting quantitative specimen measurements from the presymptomatic period, meaning these  
275 estimates may be sensitive to sampling bias. Although additional studies have reported  
276 semiquantitative metrics (cycle thresholds), these data were excluded because they cannot be  
277 compared on an absolute scale due to batch effects (36), limiting use in compound analyses.  
278 Furthermore, this study considered population-level estimates of the infectious periods, viability  
279 proportions and rate profiles for respiratory particles, which omit individual or environmental  
280 variation. Distinctions in phonetic tendencies and, especially for young children, respiratory  
281 capacity lead to variation in particle emission rates (37). Some patients shed SARS-CoV-2 with  
282 diminishing viability soon after symptom onset (21), whereas others produce replication-  
283 competent virus for weeks (38). It remains unclear how case characteristics and environmental  
284 factors affect the viability dynamics of SARS-CoV-2.

285 Taken together, our findings provide a potential path forward for disease control. They  
286 support aerosol spread as a transmission mode for SARS-CoV-2, including for conditional  
287 superspreading by highly infectious cases. However, with short durations of stay in well-  
288 ventilated areas, the exposure risk for aerosols, including long-range and buoyant ones, remains

289 correlated with proximity to infectious cases (2, 4). Strategies to abate infection should limit  
290 crowd numbers and duration of stay while reinforcing distancing, low voice amplitudes and  
291 widespread mask usage; well-ventilated settings can be recognized as lower risk venues.  
292 Coughing can shed considerable quantities of virions, while rVL tends to peak at 1 DFSO and  
293 can be high throughout the infectious period. Thus, immediate, sustained self-isolation upon  
294 illness is crucial to curb transmission from symptomatic cases. Collectively, our analyses  
295 highlight the role of infections with high rVLs in propelling the COVID-19 pandemic. While  
296 diagnosing COVID-19, qRT-PCR can also triage contact tracing, prioritizing these patients: for  
297 nasopharyngeal swabs immersed in 1 ml of transport media,  $\geq 7.14$  (95% CI: 7.07-7.22)  $\log_{10}$   
298 copies/ml corresponds to the top 20% of COVID-19 cases. Doing so may identify asymptomatic  
299 and presymptomatic infections more efficiently, a key step towards mitigation as the pandemic  
300 continues.

**Data and materials availability:** The systematic dataset and model outputs from this study are uploaded to Zenodo (<https://zenodo.org/record/4266560>). The code generated during this study is available at GitHub (<https://github.com/paulzchen/sars2-heterogeneity>). Search strategies for the systematic review are shown in Tables S1 to S5. The systematic review protocol was prospectively registered on PROSPERO (registration number, CRD42020204637).

781

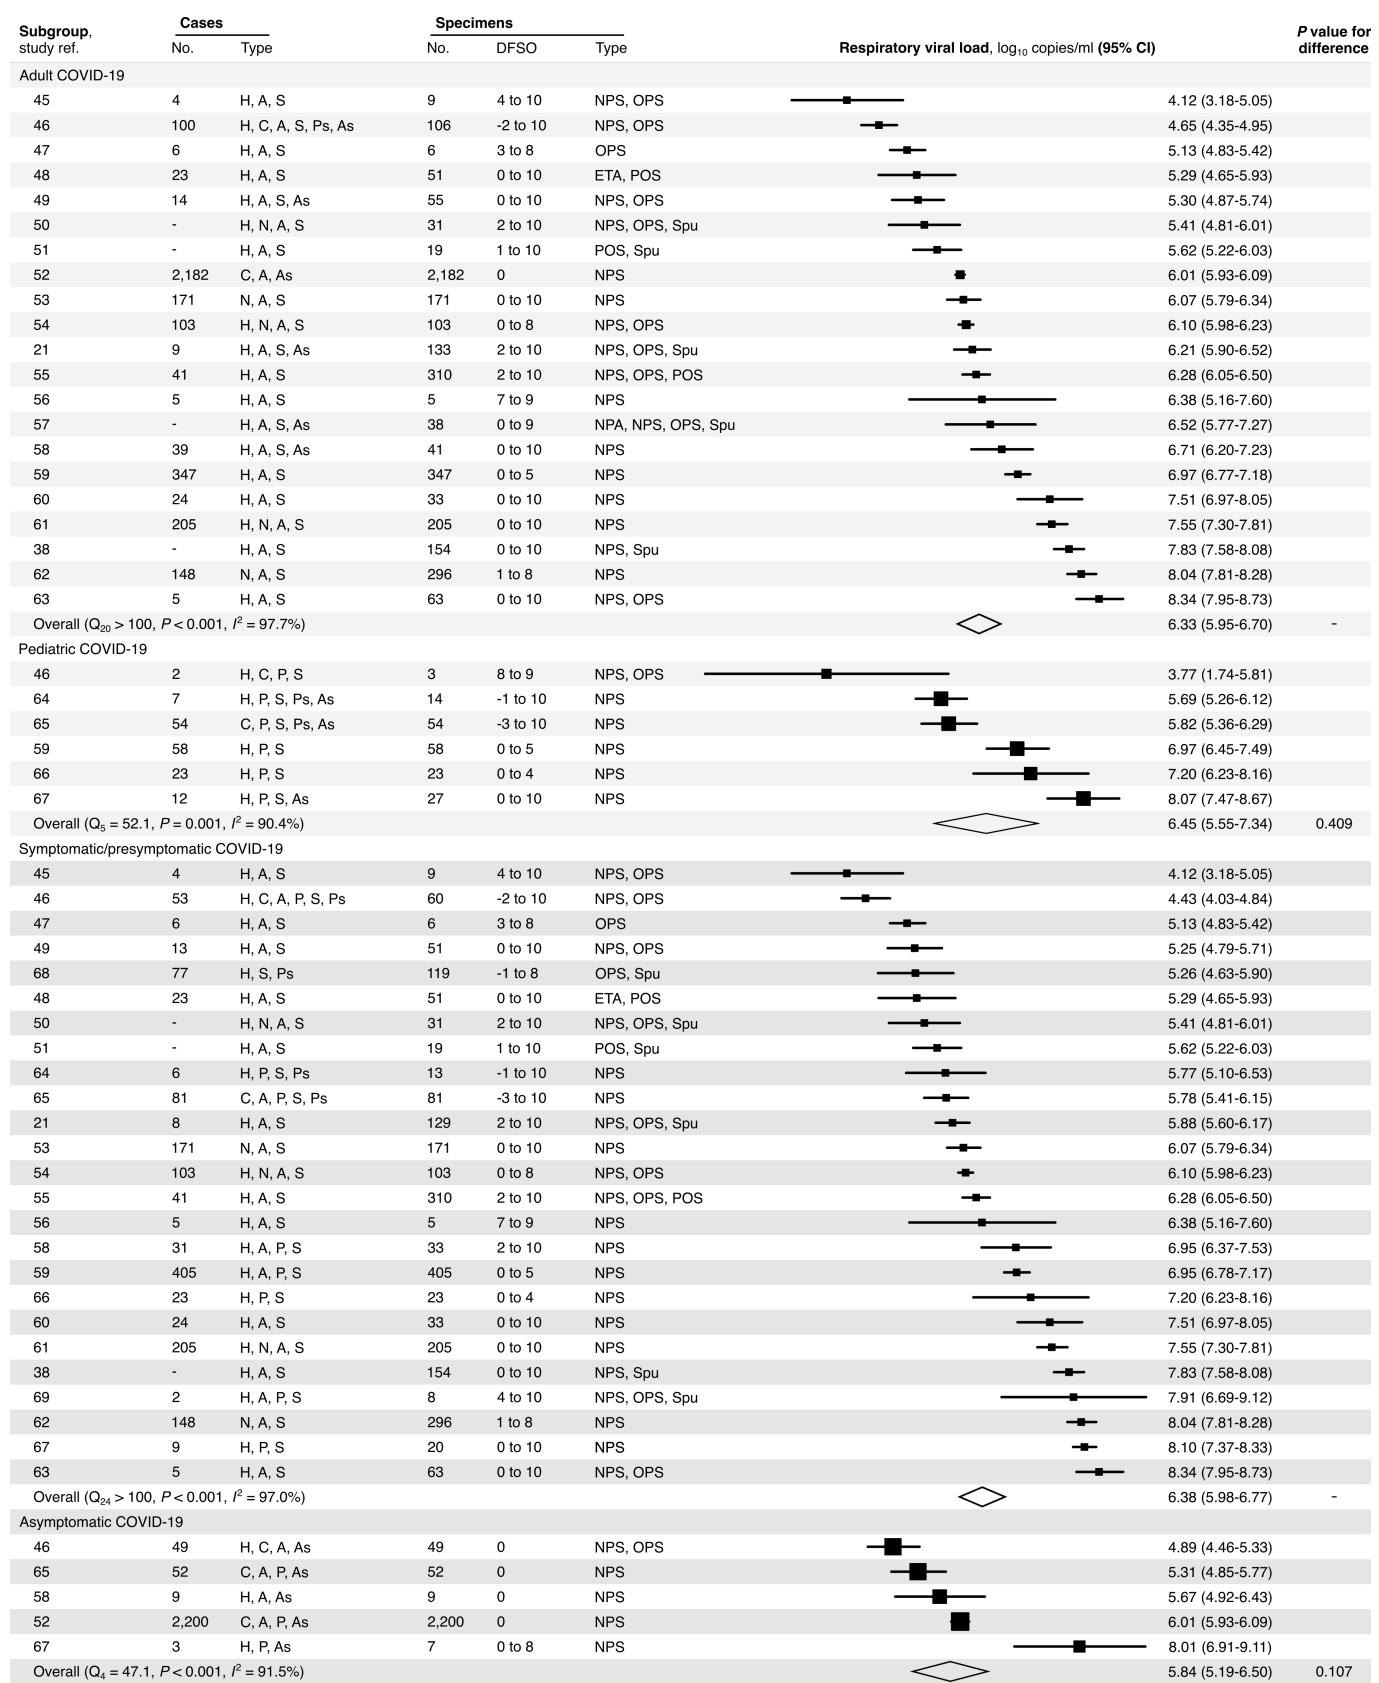

782 **Fig. 1. Development of the systematic dataset.**

783

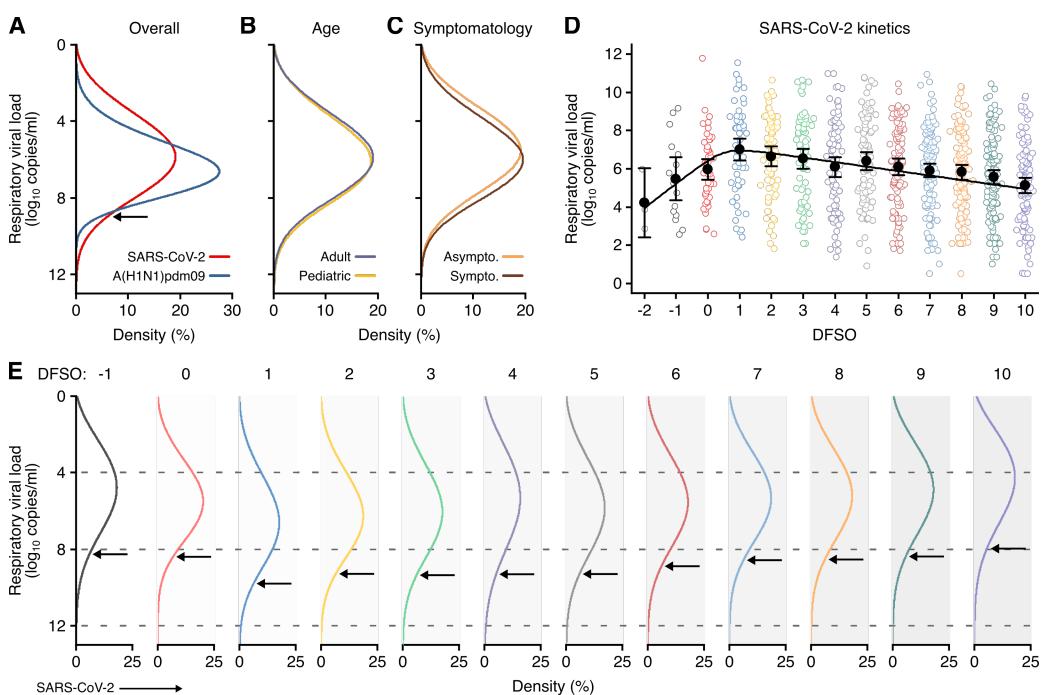

784

785 **Fig. 2. Association of overdispersion in SARS-CoV-2, SARS-CoV-1 and A(H1N1)pdm09**  
786 **transmissibility with heterogeneity in rVL.** Meta-regression of dispersion parameter ( $k$ ) with  
787 the standard deviation (SD) of respiratory viral loads (rVLs) from contributing studies with low  
788 risk of bias (Pearson's  $r = -0.73$ ). Pooled estimates of  $k$  were determined from the literature for  
789 each infection. Blue, red and yellow circles denote A(H1N1)pdm09 ( $N = 22$ ), COVID-19 ( $N =$   
790 23) and SARS ( $N = 7$ ) studies, respectively. Circle sizes denote weighting in the meta-regression.  
791 The  $P$ -value was obtained using the meta-regression slope  $t$ -test.

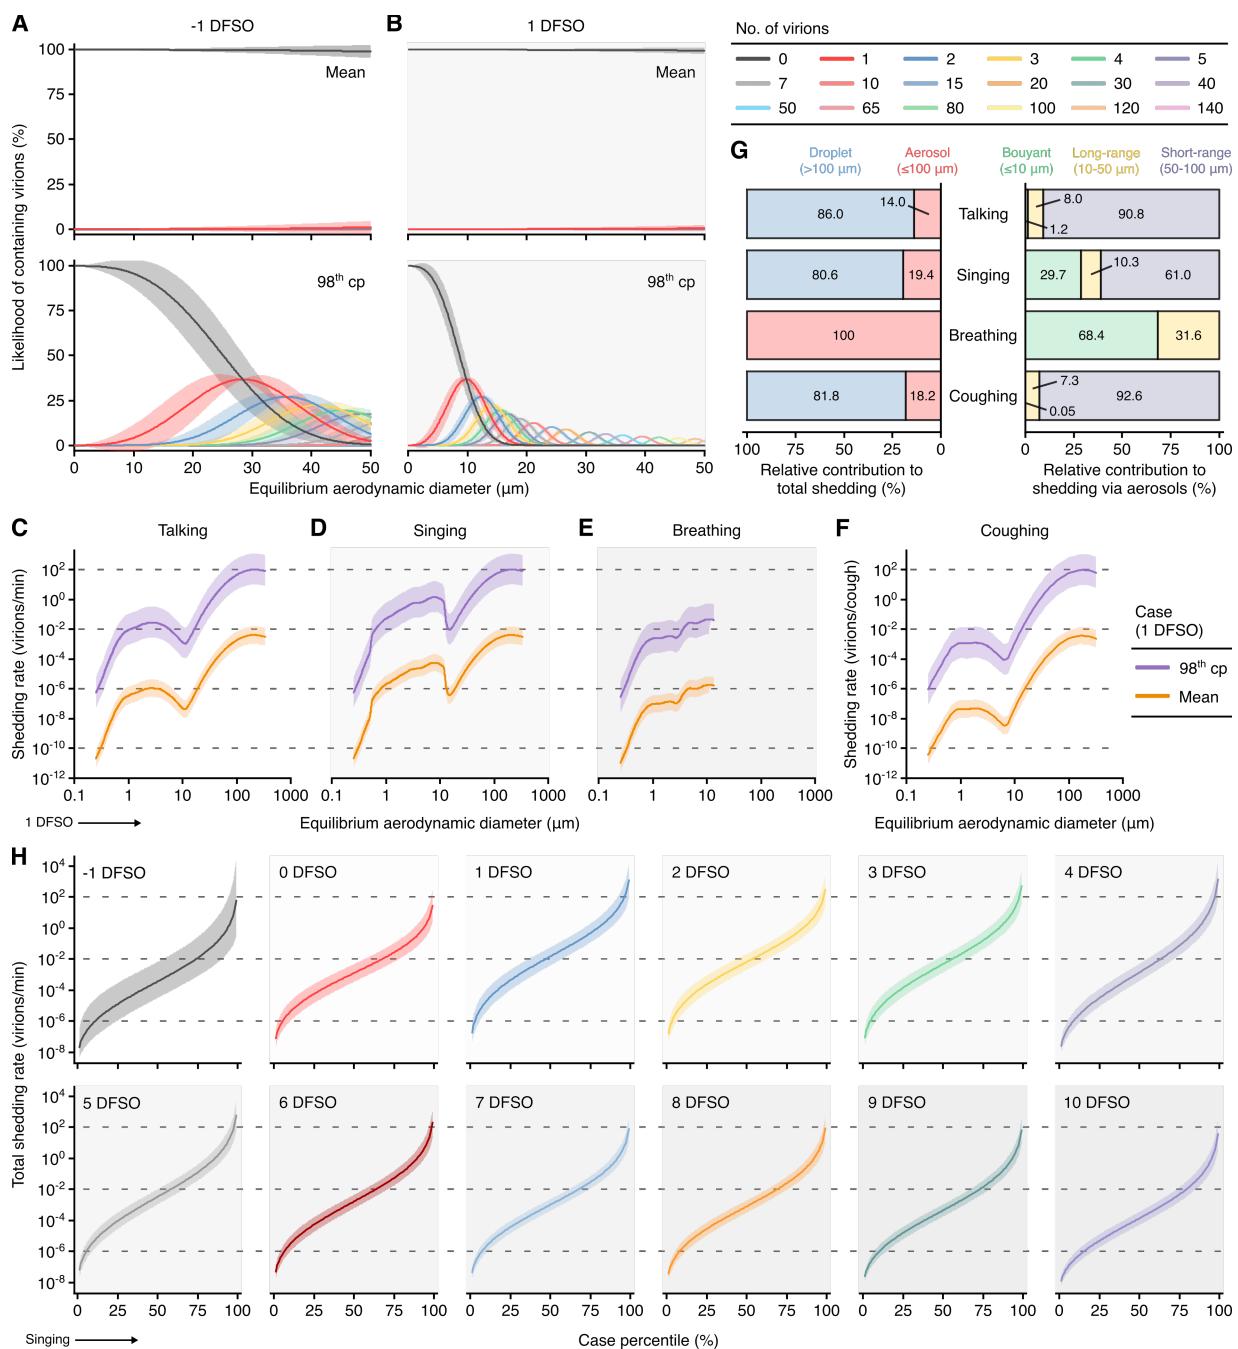

793     **Fig. 3. Subgroup analyses of SARS-CoV-2 rVL during the infectious period.** Random-  
794     effects meta-analyses comparing the expected respiratory viral loads (rVLs) of adult ( $\geq 18$  years  
795     old) COVID-19 cases with pediatric ( $< 18$  years old) ones (top) and symptomatic/presymptomatic  
796     infections with asymptomatic ones (bottom) during the infectious period. Quantitative rVLs refer  
797     to virus concentrations in the respiratory tract. Case types: hospitalized (H), not admitted (N),  
798     community (C), adult (A), pediatric (P), symptomatic (S), presymptomatic (Ps) and  
799     asymptomatic (As). Specimen types: endotracheal aspirate (ETA), nasopharyngeal aspirate  
800     (NPA), nasopharyngeal swab (NPS), oropharyngeal swab (OPS), posterior oropharyngeal saliva  
801     (POS) and sputum (Spu). Dashes denote case numbers that were not obtained. Box sizes denote  
802     weighting in the overall estimates. Between-study heterogeneity was assessed using the  $P$ -value  
803     from Cochran's  $Q$  test and the  $I^2$  statistic. One-sided Welch's  $t$ -tests compared expected rVLs  
804     between the COVID-19 subgroups (non-significance,  $P > 0.05$ ).

805

Fig. 4. Heterogeneity and kinetics of SARS-CoV-2 rVL. (A) Estimated distribution of respiratory viral load (rVL) for SARS-CoV-2 ( $N = 3,820$  samples from  $N = 25$  studies) and A(H1N1)pdm09 ( $N = 512$  samples from  $N = 10$  studies) throughout the infectious periods. (B) and (C) Estimated distribution of SARS-CoV-2 rVL for adult ( $N = 3,573$  samples from  $N = 19$  studies) and pediatric ( $N = 186$  samples from  $N = 8$  studies) (B) and asymptomatic ( $N = 2,221$  samples from  $N = 7$  studies) and symptomatic/presymptomatic ( $N = 1,560$  samples from  $N = 21$  studies) (C) COVID-19 cases. (D) SARS-CoV-2 rVLs fitted to a mechanistic model of viral kinetics (black curve,  $r^2 = 0.88$  for mean estimates). Filled circles and bars depict mean estimates and 95% CIs. Open circles show the entirety of individual sample data over days from symptom onset (DFSO) (left to right,  $N = 3, 15, 48, 59, 70, 73, 83, 92, 105, 133, 123, 128$  and 112 samples from  $N = 20$  studies). (E) Estimated distributions of SARS-CoV-2 rVL across DFSO. Weibull distributions were fitted on the entirety of individual sample data for the virus (A), subgroup (B)

818 and C) or DFSO (E) in the systematic dataset. Arrows denote 90<sup>th</sup> case percentiles for SARS-  
819 CoV-2 rVL distributions (A and E).

820

Fig. 5. Heterogeneity in shedding SARS-CoV-2 via droplets and aerosols. (A and B)

821 Estimated likelihood of respiratory particles containing viable SARS-CoV-2 when expelled by  
 822 the mean (top) or 98<sup>th</sup> case percentile (cp) (bottom) COVID-19 cases at -1 (A) or 1 (B) days from  
 823 symptom onset (DFSO). For higher no. of virions, some likelihood curves were omitted to aid  
 824

825 visualization. When the likelihood for 0 virions approaches 0%, particles are expected to contain  
826 at least one viable copy. **(C to F)** Rate that the mean and 98<sup>th</sup>-cp COVID-19 cases at 1 DFSO  
827 shed viable SARS-CoV-2 by talking (C), singing (D), breathing (E) or coughing (F) over particle  
828 size. **(G)** Relative contributions of droplets and aerosols to shedding virions for each respiratory  
829 activity (left). Relative contribution of buoyant, long-range and short-range aerosols to shedding  
830 virions via aerosols for each respiratory activity (right). **(H)** Case heterogeneity in the total  
831 shedding rate (over all particle sizes) of virions via singing across the infectious period. Earlier  
832 presymptomatic days were excluded based on limited data. Data range between the 1<sup>st</sup> and 99<sup>th</sup>  
833 cps. Lines and bands represent estimates and 95% CIs, respectively, for estimated likelihoods or  
834 Poisson means.
