Contributions: TCR drafted the article and all authors revised it for critical content.

**Funding:** This project was funded by the NERC-CSO-MRC call "Improving Health with Environmental Data" (NE/P010849/1).

**Manuscript statistics:** article body word count of 4103 plus an abstract of 246 words, one text box, five tables, three figures, two supplementary figures, and one supplementary table.

# 1 ABSTRACT

2	Background: Air pollution has been consistently linked with dementia and cognitive decline.
3	However, it is unclear whether risk is accumulated through long-term exposure or whether
4	there are sensitive/critical periods. A key barrier to clarifying this relationship is the dearth of
5	historical air pollution data. Objective: To demonstrate the feasibility of modelling historical
6	air pollution data and using them in epidemiological models. Methods: Using the EMEP4UK
7	atmospheric chemistry transport model, we modelled historical fine particulate matter ( $PM_{2.5}$ )
8	concentrations for the years 1935, 1950, 1970, 1980, and 1990 and combined these with
9	contemporary modelled data from 2001 to estimate life course exposure in 572 participants in
10	the Lothian Birth Cohort 1936 with lifetime residential history recorded. Linear regression
11	and latent growth models were constructed using cognitive ability (IQ) measured by the
12	Moray House Test at the ages of 11, 70, 76, and 79 years to explore the effects of historical air
13	pollution exposure. Covariates included sex, IQ at age 11 years, social class, and smoking.
14	Results: Higher air pollution modelled for 1935 (when participants would have been <i>in utero</i> )
15	was associated with worse change in IQ from age 11-70 years ( $\beta$ =-0.006, SE=0.002, P=0.03)
16	but not cognitive trajectories from age 70-79 years (P>0.05). There was no support for other
17	critical/sensitive periods of exposure or an accumulation of risk (all P>0.05). Conclusions:
18	The life course paradigm is essential in understanding cognitive decline and this is the first
19	study to examine life course air pollution exposure in relation to cognitive health.

22 epidemiology, atmospheric composition

# 23 INTRODUCTION

24 Dementia is a global public health crisis with almost 47 million people affected in 2015 and 25 almost 10 million new cases every year, leading to a projected prevalence of over 130 million 26 by 2050.[1] The brain changes which lead to many dementias – including the most common 27 form, Alzheimer's dementia – begin in midlife and only manifest in later life.[2] Dementia 28 prevention is now a worldwide priority and accepted risk factors include lower levels of 29 educational attainment (in early life), cardiovascular disease risk factors (with hypertension 30 and obesity particularly highlighted in mid-life), depression, hearing loss, and possession of the 31 APOE £4 allele.[3] A recent Lancet Commission report and other analyses have estimated 32 that approximately a third of dementia risk can be explained by these common risk factors. [4, 33 5] With genetic factors (most prominently APOE  $\varepsilon_4$  carriage) explaining approximately 34 another third, [6] this leaves around a third of dementia risk unexplained. However, there is 35 also evidence linking a number of environmental risk factors with dementia which might 36 account for some of this unexplained risk.[7] The risk factor for which there is strongest 37 evidence is air pollution. [8, 9] However, the field has been criticised since studies to date have 38 lacked long-term (i.e. whole life) assessment of both exposure and outcome.[10] Thus, no 39 light has yet been shed on the question of *when* in the life-course exposure to air pollution is 40 most harmful to the brain. Recent papers describing "long-term exposure" to air pollution only 41 estimated air pollution exposure at one time point.[11, 12] Indeed, answering this question 42 from a life-course epidemiology perspective is hampered by both a dearth of available air 43 pollution data from earlier than a few decades ago, when systematic long-term monitoring of 44 atmospheric concentrations was implemented and limited information about the geographical 45 location of study participants over their lives.[13] Therefore, we modelled air pollution data 46 (fine particulate matter, with an aerodynamic diameter of  $2.5\mu$ m or smaller; PM<sub>2.5</sub>) for

47 multiple time periods and linked these with the Lothian Birth Cohort 1936 (LBC1936) — for
48 whom lifetime residential history is available — to investigate links between air pollution and
49 cognitive change over more than six decades.

50

#### 51 MATERIALS & METHODS

#### 52 Study participants

53 The LBC1936 is a well-established cohort study, originally comprising 1091 men and women

aged approximately 70 years at recruitment. Almost all sat the Moray House Test (MHT) of

55 general cognitive ability in the Scottish Mental Survey in 1947 when they were aged about 11

56 years. [14] Thus, general intelligence data are available for almost all participants at ages 11

57 years, and repeatedly from approximately 70 years onwards. In the present study, we used data

from waves 1, 3 and 4 when participants had mean ages of 69.5 (SD=0.8), 76.3 (0.7), and

59 79.3 (0.6) years respectively; the MHT was not administered in wave 2. We operationalised

60 cognitive function in the same way as previous studies, adjusting for age in days and

61 standardising to an IQ-type score with mean 100 and SD 15.[15] In line with previous

62 analyses, change in IQ score was computed as the standardised residual from a linear

63 regression model with age 11 IQ as the independent variable and age 70 IQ as the dependent

64 variable; this is superior to computing the arithmetic difference.[16, 17]

65

66 In 2014, surviving LBC1936 participants were asked to complete a lifetime residential

67 questionnaire and 593 of 704 approached provided usable life grid data (full addresses) which

**68** were geocoded to latitude and longitude. [15] Participants had a mean (SD) 11.3 (2.9)

69 separate locations throughout life, ranging from six to 27, with the years they lived there also

70 recorded. Each location was allocated to the closest time period for which air pollution data

71	were available: 1935 (location year 1942 or earlier); 1950 (1943-1959); 1970 (1960-1975);
72	1980 (1976-1985); 1990 (1986-1995); or 2001 (1995-2004); locations after 2004 were
73	excluded to avoid overlap with cognitive testing (wave 1 of the LBC1936 took place from
74	2004-2007[14]). Participants may have had more than one location allocated to each time
75	point — e.g., all locations between the years 1995 and 2004 would be allocated to the 2001
76	time point. Thus, participants had up to ten locations per time point (mean [SD] values
77	ranged from 1.11 [0.34] locations recorded in 2001 to 3.38 [1.33] locations in 1970). Twenty
78	one participants (3.5%) were missing location data for at least one time point, leaving 572 in
79	the final sample who had location (and therefore air pollution) data available for every time
80	point.
81	
82	Other covariate data available in the LBC1936 and used in the models included sex, parental
83	occupational social class (using the Registrar General 1951 classification from I to V[18]), and
84	self-reported smoking status (current smoker at wave 1 or non-/ex-smoker).
85	
86	Air pollution modelling
87	The EMEP4UK atmospheric chemistry transport model (rv4.3 for 1970-2010 and rv4.10 for
88	1935/50) [19] was used to model historical ambient concentrations of fine particulate matter
89	$(PM_{2.5})$ for the years 1935, 1950, 1970, 1980, and 1990 which were combined with
90	contemporary modelled data from 2000 onwards and residential histories to estimate life
91	course exposure. The EMEP4UK model setup, geographical coverage, and configuration used
92	here has been described previously. [20, 21] The model covers the European Union with a
93	horizontal resolution of 0.5° x 0.5° used to provide the boundary condition for a nested UK
94	domain (resolution of 0.055° x 0.055°). The modelled $PM_{2.5}$ and other key air pollutant

95	concentrations are routinely validated against observations across UK monitoring
96	networks[20-25] and have been used for the assessment of population exposure over longer
97	time scales in other studies for the period 1970 to 2010.[26] Emission data have been
98	identified as key sources of uncertainty in modelling historic air pollution. A detailed
99	assessment of sensitivity and uncertainty of the Atmospheric Chemistry Transport Models
100	(ACTM) applied in this study has been published elsewhere.[27]
101	
102	UK-specific gridded emissions of nitrogen oxides (NO $_x$ ), sulphur oxides (SO $_x$ ), ammonia
103	(NH $_3$ ), non-methane volatile organic compounds (NMVOCs), carbon monoxide (CO), and
104	coarse ( $PM_{10}$ ) and fine ( $PM_{2.5}$ ) particulate matter — all necessary for the atmospheric
105	composition calculations — were produced for the target years on a nominal 1km x 1km grid
106	covering the United Kingdom. Emissions data were internally re-projected and processed by
107	the EMEMP4UK model to provide output concentration data at the model grid resolution of
108	0.055° x 0.055° resolution (~5km x 6km) for the UK. The concentrations of $PM_{2.5}$ calculated
109	by the EMEP4UK model were used in conjunction with the residential history data (as
110	described above). The sources of primary emitted PM are varied but the main contributors are
111	essentially fuel combustion (from all sources) and the use of any mobile machinery, including
112	road traffic. This is in contrast to secondary produced PM — such as ammonium sulphate
113	which is formed by the interaction of ammonia gas and sulphur dioxide — which are strongly
114	linked to specific sectors, such as $\mathrm{SO}_{\mathrm{x}}$ (energy) and $\mathrm{NH}_3$ (agriculture). The PM components
115	included in the EMEP4UK model are; primary PM, secondary inorganic and organic aerosols,
116	sea salt, and mineral dust.[22] Although this work is focused on the UK the EMEP4UK
117	requires emission data for the whole of Europe to account for the transboundary
118	imports/export. EU data were kindly supplied at a 50km x 50km resolution. [28, 29] The

EMEP4UK model is driven by 3D hourly meteorology calculated by the weather and research

119

120	forecast model.[30] The meteorological year used for the 1935 and 1950 emission scenario
121	was the year 2014, for the 1970, 1980, 1990 emission scenario was the year 2012, and for the
122	2001 emission scenario the year was 2001.
123	
124	For the years 1970, 1980 and 1990, emission data in the official UK inventory, the National
125	Atmospheric Emissions Inventory,[31] were used to scale 2017 spatial distributions (1km x
126	1km resolution) of sectoral totals per pollutant, reported via the Selected Nomenclature for
127	sources of Air Pollution system (SNAP sectors). While the use of contemporary distributions
128	back to 1970 is imperfect, the majority of the time series had the best possible emissions
129	estimates per sector. Emissions for 1950 were estimated and distributed in the Long Term
130	Large Scale project, [32] while the 1935 emissions were a scaled version of the 1950
131	distributions based upon activity data research, using the same spatial methods. Non-NH $_3$
132	activity data prior to 1970 are largely a reflection of the use of fossil fuels such as coal and of
133	oil-derived products such as diesel (DERV); coal usage in the UK had a double peak either
134	side of World War Two before a rapid decline in the 1960s. Agricultural activity data such as
135	animal numbers, principally associated with emissions of $NH_3$ , were derived from the Vision of
136	Britain database. [33] For source strength emission factors (EFs), many were similar to those
137	used by the UK National Atmospheric Emission Inventory (NAEI) in 1970 while in terms of
138	the spatial distribution of pre-1970 data, the principal differences from the NAEI distributions
139	were: power stations relevant to the time period were mapped and the distribution of
140	industrial activity was tied to census employment data.[32]
141	

142	Raster files for each location year (1935, 1950, 1970, 1980, 1990, and 2001) were read into
143	the R statistical computing environment version 4.0.2 using the raster package.[34] The
144	latitude and longitude for each location were used to derive values from these raster files for
145	each participant at each time point. Since participants may have had multiple locations within
146	each time band, the unweighted mean of these multiple values per time point was calculated
147	and used in the analyses as the value for that participant at that time point. For example, the
148	mean of all the air pollution values corresponding to locations recorded between the years
149	1995 and 2004 would be allocated to the 2001 time point for an individual participant. For
150	the purposes of sensitivity analyses, we also computed the maximum value for each time point
151	per participant and the 90% percentile value.
152	
153	Statistical modelling
154	Following the convention in previous LBC1936 analyses, we modelled change in IQ score
155	from age 11 to age 70 years separately from changes between the ages of 70, 76, and 79 years.
156	The former used a linear regression model of <i>in utero</i> air pollution exposure (i.e., using $PM_{2.5}$
157	data for 1935; this was the only measurement of air pollution which predated the MHT
158	administration at age 11 years) and residualised change in IQ score from age 11 to age 70
159	years in the R statistical computing environment version 4.0.2. We adjusted this model for
160	sex, parental occupation, and smoking status.
161	
162	To estimate linear late life cognitive trajectories, we fitted latent growth models to IQ scores
163	from ages 70, 76, and 79 years to estimate the average population cognitive curves. These
164	longitudinal models permit estimation of the outcome's mean and individual trajectories while
165	permitting the inclusion of predictors (time-invariant or time-varying) to study their

166	association with curve parameters such as the intercept and slope parameters. Latent growth
167	models were estimated using maximum likelihood under a 'missing at random' missing data
168	assumption. All latent growth models were estimated using MPLUS.[35]
169	
170	We summarise the models fitted in Figure 1, in which observed data are represented within
171	rectangles, and latent variables such as the model's intercept and slope are represented within
172	circles. The one-way arrows indicate that the variable at the end of the arrow is explained in
173	the model by the variable at the beginning of the arrow. Often in such figures, two-way curved
174	arrows indicate covariances but as is commonly done – in order to simplify the figure – we
175	have omitted these arrows here as well as the arrows that indicate error terms.
176	
177	Life course models
178	The two main models in life course epidemiology are critical/sensitive periods and
179	accumulation of risk. [2] To evaluate questions about any $critical/sensitive \ period(s)$ of air
180	pollution exposure and maximise the use of pollution data collected over the life course, we
181	estimated late life trajectories of IQ scores at ages 70, 76 and 79 years, adjusting the intercept
182	and rate of change for air pollution measures collected at different ages in the life course, age
183	11 IQ scores, sex, parental social class, and smoking status. Specifically, we adjusted the
184	models separately for PM <sub>2.5</sub> in 1935, 1950, 1970, 1980, 1990, or 2001. Figure 1a depicts an
185	example of the critical/sensitive period model fitted here.
186	
187	In order to evaluate an accumulation of risk model, we estimated a series of latent growth
188	models similar to the previous ones, adjusting the level and rate of change for variables
189	defined as the sum of air pollution to which the individual was exposed up to different stages

190	in life. That is, we added <i>in utero</i> air pollution measures (i.e., from 1935) to air pollution
191	measures collected in 1950 to derive an indicator of early life exposure; the sum of air
192	pollution measures from 1935 to 1970 covered early life to young adulthood; additionally
193	adding pollution from 1980 encompassed early life to mid-adulthood; the addition of air
194	pollution in 1990 covered early life to late adulthood; finally, adding air pollution from 2001
195	covered early life to later life. Figure 1b depicts an example of the accumulation period
196	model fitted here. Text Box 1 summarises the models used in the present analyses.
197	
198	RESULTS
199	A total of 572 LBC1936 participants were included in the present analyses. Their
200	characteristics are summarised in Table 1. Briefly, just under half were female, and had
201	completed more than compulsory education. Just over a quarter had parents from
202	occupational social classes I or II (i.e., less deprived), and about half were smokers at the time
203	of recruitment to the LBC1936. Comparing the 572 LBC1936 participants for whom we had
204	location (and therefore air pollution) data with the 519 participants excluded from these
205	analyses revealed no major differences.
206	
207	Air pollution
208	Table 2 shows the average air pollution estimates for the LBC1936 participants and
209	Supplementary Figure 1 shows the distribution of air pollution exposure at each time period.
210	Supplementary Figure 2 shows participants' $PM_{2.5}$ exposure changes over time and
211	Supplementary Table 1 shows the correlations between individuals' $PM_{2.5}$ exposure ranking
212	at different time points. Rankings varied over time — likely due more to participants moving
213	than the relative ranking of areas changing — but were more closely correlated when closer in

- time, suggesting it is feasible to explore critical/sensitive time periods. Figure 2 shows the
- 215 modelled PM<sub>2.5</sub> values for Scotland in 1935; the urban centres are clearly visible.

217	Is in utero air pollution exposure associated with cognitive trajectories over the life course?
218	Results from this model are presented in Table 3a, where the potential impact of air pollution
219	measured in 1935 on the residualised change in IQ between the ages of 11 and 70 years,
220	controlling for sex, parental social, class, and smoking was explored. There was a small
221	association between higher levels of air pollution exposure in 1935 and in utero and a poorer
222	IQ trajectory in IQ from 11 to 70 years ( $\beta$ =-0.006 IQ point per 1 µg/m <sup>3</sup> increase in PM <sub>2.5</sub> ,
223	SE=0.002, P=0.03).
224	
225	Is in utero exposure to air pollution associated with late life cognitive trajectories?
226	Figure 1a depicts the model that estimates linear changes in IQ scores between the ages of 70,
227	76, and 79 years. In this model, the intercept represents the average IQ score at age 70 for a
228	reference individual (a male whose father had a skilled job, who was exposed in utero to
229	average levels of pollution, and who had an average IQ score at age 11 years) and the slope,

 $\mathbf{230}$   $\$  the average rate of change of IQ scores from age 70 to 79 years. There was a small association

231 between air pollution values for 1935 and the intercept (IQ score at age 70 years), albeit only

232 of borderline statistical significance at conventional levels (P=0.06), but no association with

rate of change in IQ score from age 70 to 79 years (P=0.36; Table 3b).

234

235 Critical/sensitive period

236 For the sake of brevity, Table 4 only contains estimates of the average value of IQ scores at

age 70, their rate of decline until age 79 (for a reference individual, as defined above) and

- 238 estimates of the association of air pollution exposure at each of the life course time points
- 239 (apart from 1935 which was reported above) with IQ level at age 70 and rate of change
- 240 (Figure 1b). No period of air pollution exposure had an effect on either the intercept or the

241	rate of change of the models which reached statistical significance at conventional levels (all
242	P>0.05).

243

244	Accumulation model
245	Summary results of the models are presented in Table 5, where estimates of average IQ level
246	at age 70, average IQ linear rate of change from that same age, and coefficients of the
247	association between air pollution exposure at different stages of life with these parameters are
248	presented. None of the risk periods had an effect on either the intercept or the rate of change
249	of the models which reached statistical significance at conventional levels (all P>0.05). Our
250	findings were robust to the sensitivity analyses varying the aggregation method used for
251	multiple air pollution values.
252	
253	DISCUSSION
254	Our main finding is that it is feasible to model historical air pollutant concentration data and
255	incorporate them in epidemiological models to explore the influence of exposure to air
256	pollution across the life course. We found little evidence that exposure to air pollution at
257	different stages of the life course was associated with cognitive health and there was no
258	support for an accumulation of risk. There was some evidence of exposure to air pollution in
259	utero being associated with worse cognitive change between the ages of 11 and 70 years, but
260	the effect size was small ( $\beta$ =-0.006). In particular we would highlight that these results have
261	large degrees of uncertainties, considering the various methodologies used to produce the
262	different air pollution concentration estimates due the wide range of emissions estimates,
263	particularly for earlier estimates which have a lack of measured air quality data against which
264	to be evaluated.

265

# **266** Comparison with other literature

267	As noted in the introduction, there is a growing wealth of literature on the association
268	between air pollution and subsequent cognitive impairment and dementia, but the majority of
269	publications share the same shortcomings: [10] (1) an inability to explore when in the life
270	course exposure to air pollution has the most impact?; (2) which pollutant(s) or components
271	are most important?; and (3) since dementia describes a heterogeneous group of conditions,
272	which are most affected by exposure to air pollution?
273	
274	Investigators from the Washington Heights–Inwood Community Aging Project (WHICAP)
275	and the Northern Manhattan Study (NOMAS) recently reported their findings of the impact
276	of "long-term" exposure to air pollution (nitrogen dioxide, $PM_{10}$ , and $PM_{2.5}$ ), but these
277	participants (aged 65 years or older) were only recruited in the early 1990s and only their
278	residential address at the time of recruitment was used to estimate their exposure to air
279	pollution; air pollution values for the year before recruitment were used as the exposure.[11,
280	12] Our study was able to track migration and movement throughout the life course,
281	combined with modelled atmospheric concentration data covering most of the twentieth
282	century, to give a much better estimate of each person's exposure to air pollution at different
283	points in their lives.
284	
285	Limitations and Strengths
286	Referring to the three criticisms of the air pollution literature described above, [10] the present
287	study could potentially shed some provisional light on the first (when in the life course is most
288	important), but not the second or third. A decision was taken early on to minimise the impact

289	of multiple testing by restricting the pilot modelling (of 1935 data) to a single pollutant; $PM_{2.5}$
290	was chosen since the majority of the literature linking air pollution and dementia focused on
291	that pollutant. Modelling other pollutants — such as smaller PM, $\mathrm{NO}_{\mathrm{x}}$ etc. — is feasible and
292	we hope to do this in the future, now that the feasibility of this approach has been
293	demonstrated.
294	
295	The collection of lifetime residential histories is rare and greatly augments the other data
296	available in the LBC1936. However, there are limitations to the approach taken
297	(retrospective collection of residential address history), including the fact that it is prone to
298	recall bias. Furthermore, only participants who were alive in 2014 were approached,
299	additionally introducing survivor bias. Finally, the accumulated $PM_{2.5}$ exposure was calculated
300	using an unweighted method – i.e. not taking into account the length of time an individual
301	lived at each address. Our main aim in the present analysis was to establish proof of concept
302	and hope that a more sophisticated weighted calculation – which could arguably be more
303	accurate – could be taken by future studies.
304	
305	Almost all participants — until 2001 — were exposed to levels of $PM_{2.5}$ in excess of the World
306	Health Organization's guidelines of a maximum annual mean of 10µg/m <sup>3</sup> .[36] For
307	comparison, approximately half of UK Biobank participants were exposed to similarly
308	excessive values at baseline (mean [SD] 10.0 [1.1])[37], in line with most of the world.[38]
309	There was a general reduction in air pollution over time — and marked step-changes between
310	some time points — but it is unclear how much of this is artefactual, relating to
311	methodological differences between the procedures used to generate these historical estimates.
312	There are inherent uncertainties at all stages of the emissions estimation process, even for the

313 present day, and many of these problems are magnified when trying to recreate an historical 314 context. The lack of measurement data to verify source strength, the lack of data regarding 315 the chemical composition of fuel and the behaviour of combustion technologies prior to 316 emissions mitigations are just some of the many issues that can influence the uncertainty. 317 From 1970 onwards, emissions uncertainties were estimated from the UK Inventory [39] while 318 for 1935 and 1950, uncertainty estimations are expert judgement. [40] Given the assumptions 319 that the fuel use data are lacking some detail (such as certain oil-based products, wood etc.), 320 combustion technology was a lot more polluting than in 1970 due to a lack of various 321 mitigating options such as scrubbers and particulate filters and that there are some missing 322 sources such as construction etc., it is very likely that the uncertainty range is asymmetric with 323 respect to the best estimate. To reflect this probable under estimation, the asymmetry was estimated to be one order of magnitude centred on the mean, that is  $\frac{1}{\sqrt{10}} < x < \sqrt{10}$ . As an 324 325 example, the emissions of PM<sub>25</sub> in 1935 were 715kt (range 226-2261kt). Whilst the 326 uncertainties were not utilised within the EMEP4UK model, it is important to note these 327 qualitative estimates and the potential impacts on the final results. Figure 3 shows the final 328 emissions estimates for all pollutants per year (2015 is displayed for context). 329 330 The focus of this paper is cognitive change rather than dementia. It is important to assess pre-331 dementia cognitive change and its determinants in their own right, but dementia is inarguably 332 important. However, there were not sufficient LBC1936 participants who had developed 333 dementia to allow meaningful models to be constructed. A comprehensive programme of

- dementia ascertainment in LBC1936 participants (who are currently in their mid-80s) is
- 335 currently underway and, once these data are available, similar models focused on dementia
- will be possible.

337

338	Statistically, the life course model (change between ages 11 and 70 years) and late life models
339	(intercept and change from 70 to 79 years) are not comparable. Furthermore, a linear
340	assumption for the late life cognitive trajectories may be too strong. It may be necessary to
341	explore more complex models, such as quadratic trajectories, but the primary aim of this study
342	was proof of concept and so we have not taken that approach here. With additional time
343	points, we could have constructed a model that would permit estimation of piecewise
344	trajectories. This may become possible as further waves of data become available — wave 5 of
345	the LBC1936 was completed last year and wave 6 was due to begin in Spring 2020 but had to
346	be delayed because of the Covid-19 pandemic.

The modelled historical air pollution data need to be refined and harmonised across different time points – and these data used to provide a robust estimate of life course exposure – but we believe that we have demonstrated the feasibility and value of this approach. However, these air pollution data will be of little value without well-characterised cohort studies with full residential histories for participants, such as are available for the LBC1936. All high quality longitudinal cohort studies should explore whether it is possible to obtain such data through record linkage or — as in the LBC1936 — self-report.

359 Conclusions

- 360 We have shown the feasibility of modelling historical air pollution data and incorporating
- 361 them in epidemiological models. This is the first step in a new area and we look forward to a
- **362** greater understanding of the life course effects of air pollution on the brain in coming years.

#### ACKNOWLEDGEMENTS

This study was funded by the "Improving Health with Environmental Data" call from the Natural Environment Research Council, the Chief Scientist Office, and the Medical Research Council (NE/P010849/1). It follows research undertaken under the Mobility, Mood, and Place research project (2013–2016), supported by Research Councils UK (EP/K037404/1) as part of the Cross-Council Lifelong Health and Wellbeing Program under Principal Investigator Catharine Ward Thompson and Co-Investigators Jamie Pearce and Niamh Shortt.

TCR and the late JMS are/were members of the Alzheimer Scotland Dementia Research Centre funded by Alzheimer Scotland. The Lothian Birth Cohort 1936 is funded by Age UK (Disconnected Mind grant). TCR, the late JMS, and IJD were members of the University of Edinburgh Centre for Cognitive Ageing & Cognitive Epidemiology (which recently closed), part of the cross council Lifelong Health and Wellbeing Initiative (MR/K026992/1). Funding from the Biotechnology and Biological Sciences Research Council and Medical Research Council is gratefully acknowledged for the latter.

Initial findings of this study were presented at the Alzheimer's Association International Conference in Chicago, 2018 (<u>https://doi.org/10.1016/j.jalz.2018.06.2861</u>).

Models adjusted for sex, age 11 IQ, parental (father's) occupation, and smoking status Coefficients ( $\beta$ ) represent the change in IQ and rate of change per 1  $\mu$ g/m<sup>3</sup> increase in PM<sub>2.5</sub>

## FIGURE LEGENDS

**Figure 1.** Directed Acyclic Graphs representing the (a) critical/sensitive period and (b) accumulation models fitted to IQ scores: life course air pollution exposure and cognitive decline in the LBC1936

**Figure 2.** Modelled particulate matter  $(PM_{2.5})$  values in 1935: life course air pollution exposure and cognitive decline in the LBC1936

**Figure 3.** Modelled emission totals (Gg) with uncertainty ranges for five air pollutants (CO, NH<sub>3</sub>, NMVOCs, NO<sub>x</sub>, and SO<sub>x</sub>), plus  $PM_{2.5}$ , across five model years (2015 is included for context) for use in the EMEP4UK model: life course air pollution exposure and cognitive decline in the LBC1936

**Figure 2.** Modelled particulate matter  $(PM_{2.5})$  values in 1935: life course air pollution exposure and cognitive decline in the LBC1936

The area displayed in the lower panel and enclosed in a box on the upper panel is the central belt of Scotland including Glasgow (left) and Edinburgh (right). Over half of the population of Scotland lives in this area.

Figure 3. Modelled emissions totals (Gg) with uncertainty ranges for five air pollutants (CO, NH<sub>3</sub>, NMVOCs, NO<sub>x</sub>, and SO<sub>x</sub>), plus PM<sub>2.5</sub>, across five model years (2015 is included for context) for use in the EMEP4UK model: life course air pollution exposure and cognitive decline in the LBC1936

Supplementary Figure 1a. Mean  $PM_{2.5}$  exposure for each participant at each time point for which air pollution concentration data were modelled: life course air pollution exposure and cognitive decline in the LBC1936

Blue dotted line — mean  $PM_{2.5}$  value; Solid red line — WHO guidelines (annual average  $\leq 10 \mu g/m^3$ )

Supplementary Figure 1b. Mean  $PM_{2.5}$  exposure for each participant at each time point for which air pollution concentration data were modelled (all plotted on the same x and y scales): life course air pollution exposure and cognitive decline in the LBC1936

Blue dotted line — mean  $PM_{2.5}$  value; Solid red line — WHO guidelines (annual average  $\leq 10 \mu g/m^3$ )

Supplementary Figure 2. Sankey diagram indicating the change in mean annual  $PM_{2.5}$  exposure within individuals over time: life course air pollution exposure and cognitive decline in the LBC1936

	1935	1950	1970	1980	1990	2001
1950	0.53	-				
1970	0.13	0.22	-			
1980	0.06	0.18	0.57	-		
1990	0.09	0.19	0.53	0.82	-	
2001	0.003	0.10	0.05	0.03	0.08	-

**Supplementary Table 1.** Correlations between  $PM_{2.5}$  exposure rankings at different time points: life course air pollution exposure and cognitive decline in the LBC1936
