1 Abstract

2 Epstein-Barr virus (EBV) is one of the most common viruses latently infecting
3 humans. Little is known about the impact of human genetic variation on the
4 large inter-individual differences observed in response to EBV infection. To
5 search for a potential imprint of host genomic variation on the EBV sequence,
6 we jointly analyzed paired viral and human genomic data from 268 HIV-
7 coinfecting individuals with CD4+ T cell count $<200/\text{mm}^3$ and elevated EBV
8 viremia. We hypothesized that the reactivated virus circulating in these patients
9 could carry sequence variants acquired during primary EBV infection, thereby
10 providing a snapshot of early adaptation to the pressure exerted on EBV by the
11 individual immune response. We searched for associations between host and
12 pathogen genetic variants, taking into account human and EBV population
13 structure. Our analyses revealed significant associations between human and
14 EBV sequence variation. Three polymorphic regions in the human genome were
15 found to be associated with EBV variation: one at the amino acid level
16 (BRLF1:p.Lys316Glu); and two at the gene level (burden testing of rare variants
17 in BALF5 and BBRF1). Our findings confirm that jointly analyzing host and
18 pathogen genomes can identify sites of genomic interactions, which could help
19 dissect pathogenic mechanisms and suggest new therapeutic avenues.

1 Introduction

2 Human genetic variation plays a key role in determining individual responses after exposure
3 to infectious agents. Even though susceptibility or resistance to a microbial challenge is the
4 final result of dynamic interactions between host, pathogen, and environment, human genetic
5 polymorphisms have been shown to have an important, directly quantifiable impact on the
6 outcome of various infections [1,2].

7 Genome-wide association studies (GWAS) have proven powerful to identify genetic regions
8 implicated in a wide range of complex traits in both health and disease [3]. In the field of
9 infectious diseases, several clinical and laboratory phenotypes have been investigated,
10 including, for example disease susceptibility [4,5], clinical outcomes [6], adaptive immunity
11 [7,8,9] or drug response [10]. In chronically infected patients, however, the pathogen genome
12 itself provides a promising complementary target to investigate the impact of host genomic
13 diversity on infection. While one part of the variation observed in pathogen DNA or RNA
14 sequence is present at the transmission event, another fraction is acquired during the course
15 of an infection, resulting at least partially from selective pressure exerted by the host response
16 on the infectious agent. The phenomenon of within-host evolution has been extensively
17 investigated for both viruses [11,12,13] and bacteria [14,11]. Pathogen genomic variation can
18 thus be considered an intermediate phenotype that is detectable as a footprint of within-host
19 evolution. This can serve as a basis for a joint association analyses of host and pathogen
20 genome variation, which we called genome-to-genome (G2G) analysis [15], a more powerful
21 approach than using a clinical outcome alone. A global description of the adaptive forces
22 acting on a pathogen genome during natural infection holds the potential to identify novel
23 therapeutic and diagnostic targets and could inform vaccine design efforts [16].

24 A G2G analysis for the quickly evolving human immunodeficiency virus (HIV) identified strong
25 associations of single nucleotide polymorphisms (SNPs) in the HLA class I region with multiple
26 amino acid variants across the viral genome [15]. More recent work showed an impact of
27 variation in the HLA class II and interferon lambda 4 (IFNL4) loci on hepatitis C virus (HCV)
28 sequence diversity [17,18,19]. While the rate of evolutionary change in RNA viruses is higher
29 than in DNA viruses [20], the latter also present considerable amounts of inter- and intra-host
30 variation. Among herpesviruses, it has been shown that human cytomegalovirus (HCMV) has
31 higher genomic variability than other DNA viruses [21]. Recent genome sequencing efforts
32 demonstrated that the same holds true for Epstein-Barr virus (EBV) [22,23].

33 EBV is a widespread human pathogen that causes infectious mononucleosis in about 10% of
34 individuals during primary infection. EBV infection occurs most often early in life, with about
35 30% of children being seropositive by age 5, 50% by age 10 and up to 80% by age 18 [24].
36 This human infecting herpesvirus has also been associated with post-transplant
37 lymphoproliferative disease [25] and could play a role in some autoimmune diseases [26,27].
38 In addition, EBV has oncogenic properties and is implicated in the pathogenesis of multiple
39 cancer types, predominantly Burkitt's lymphoma, Hodgkin's and non-Hodgkin's lymphoma,
40 nasopharyngeal carcinoma and gastric carcinoma [28,29]. More than 5% of the 2 million
41 infection-associated new cancer cases in 2008 could be attributed to EBV [30]; it was also
42 estimated to have caused 1.8% of cancer deaths in 2010, i.e. more than 140,000 cases [31].

43 The EBV genome is approximately 170 Kbp long and encodes at least 80 proteins, not all of
44 which have been definitively identified or characterized. After primary infection, the EBV
45 genome persists in B cells as multicopy episomes that replicate once per cell cycle. In this

1 latent mode, only a small subset of viral genes is expressed. Latent EBV can then reactivate
2 to a lytic cycle, which involves higher gene expression and genome amplification for packaging
3 into new infectious viral particles [32].

4 A small number of host genomic analyses of EBV infection have been recently published,
5 demonstrating that human genetic diversity plays a role in disease outcome. A study in 270
6 EBV isolates from southern China identified two non-synonymous EBV variants within the
7 *BALF2* gene that were strongly associated with the risk of nasopharyngeal carcinoma [33].
8 Another group investigated the co-evolution of worldwide EBV strains [34] and found extensive
9 linkage disequilibrium (LD) throughout EBV genomes. Furthermore, they observed that genes
10 in strong LD were enriched in immunogenic genes, suggesting adaptive immune selection and
11 epistasis. In a pediatric study of 58 Endemic Burkitt lymphoma cases and 40 healthy controls,
12 an EBV genome GWAS identified 6 associated variants in the genes *EBNA1*, *EBNA2*, *BcLF1*,
13 and *BARF1* [35]. Finally, the narrow-sense heritability of the humoral immune response
14 against EBV was estimated to be 0.28 [9,36].

15 Here, we present the first global analysis of paired human and EBV genomes. We studied full
16 EBV genomes together with their respective host genomic variation in a cohort of 268
17 immunocompromised, HIV-coinfected patients. We chose untreated HIV-coinfected patients
18 because EBV reactivation leading to viremia is more prevalent in immunosuppressed
19 individuals than in an average population. Our analysis reveals three novel host genomic loci
20 that are associated with variation in EBV amino acids or genes.

21 **Materials and Methods**

22 **Study participants, sample preparation**

23 The Swiss HIV Cohort Study (SHCS) is a nationwide, prospective cohort study of HIV-infected
24 patients that enrolled >20,000 individuals since its establishment in 1988 and prospectively
25 followed them at 6-month intervals [37]. For this project, SHCS participants were identified
26 based on written consent for human genetic testing and availability of a peripheral blood
27 mononuclear cell (PBMC) sample at time of advanced immunosuppression (i.e., with CD4+ T
28 cell count below 200/mm³) in the absence of antiretroviral treatment.

29 We obtained demographic and clinical information from the SHCS database. These included
30 sex, age, longitudinal HIV viral load results (number of RNA copies per ml of plasma),
31 longitudinal CD4+ T cell counts (number of cells per mm³ of blood), and history of opportunistic
32 infections.

33 The SHCS has been approved by the Ethics Committees of all participating institutions
34 (Ethikkommission Nordwest- und Zentralschweiz, EKNZ; Kantonale Ethikkommission Bern;
35 Ethikkommission Ostschweiz, EKOS; Ethikkommission Zürich; Commission cantonale
36 d'éthique de la recherche sur l'être humain, Genève, CCER; Commission cantonale d'éthique
37 de la recherche sur l'être humain, Vaud, CER-VD; Comitato etico cantonale Ticino). Each
38 study participant provided written informed consent for genetic testing, and all research was
39 performed in accordance with relevant guidelines and regulations.

1 EBV genome quantification, enrichment and sequencing

2 DNA was extracted from PBMCs using the MagNA Pure 96 DNA and the Viral NA Small
3 Volume Kit (Roche, Basel, Switzerland). Cellular EBV load was then determined using
4 quantitative real-time PCR. Samples that yielded > 100 viral copies / ul were selected for EBV
5 genome sequencing.

6 We used the previously described enrichment procedure to increase the relative abundance
7 of EBV compared to host DNA [38]. Shortly, baits covering the EBV type 1 and 2 reference
8 genomes were used to selectively capture viral DNA according to the SureSelect Illumina
9 paired-end sequencing library protocol. Samples were then multiplexed and sequenced on an
10 Illumina NextSeq sequencer [38].

11 EBV sequence analyses

12 We chose a reference-based approach to call variants in the pathogen data. Since EBNA-2
13 and EBNA-3s are highly variable between EBV-1 and EBV-2 strains, we suspected that reads
14 sequenced from these genes would map only to their corresponding type. In an attempt to
15 attenuate the reference-bias this could cause, we constructed two references, one with the
16 whole genome of the EBV-1 strain B95-8 (accession NC_007605) and EBNA-2 and EBNA-3s
17 sequences from EBV-2 strain AG876 (accession NC_009334) and another one with the whole
18 genome of AG876 with the EBNA-2 and EBNA-3s sequences of B95-8.

19 The read libraries were processed through Trimmomatic [39] to remove remnant PCR tags,
20 TagDust [40] to eliminate low complexity reads and CD-HIT [41] to filter out duplicate reads.
21 The remaining sequence reads were aligned to the constructs described in the previous
22 paragraph. Following GATK best practices [42,43], we mapped the read libraries using BWA
23 mem [44]. We cleaned the regions around InDels using GATK v3.8's IndelRealigner [45]. As
24 a last pre-processing step, we applied bwa-postalt.js, a BWA script that adjusts mapping
25 quality score in function of alignments on ALT haplotypes.

26 Because patients can be infected by multiple EBV strains [46], we used BWA's ALT-aware
27 ability. In short, reads mapping to an ALT contig were always marked as supplementary
28 alignment, regardless of mapping quality, unless they did not map to the primary assembly.
29 This makes it easy to find unambiguously mapped reads, which we used as markers to
30 quantify type 1 and type 2 EBV reads in all samples.

$$r1 = \frac{\# T1}{(\# T1 + \# T2) \cdot L1}$$

$$r2 = \frac{\# T2}{(\# T1 + \# T2) \cdot L2}$$

31 $r = r1 - r2$

32 where #T1 and #T2 are the unambiguous read counts against type 1 and 2 haplotypes,
33 respectively, L1 and L2 are the length of type 1 and 2 haplotypes, respectively, and r1 and r2
34 are the type 1 and 2 ratios, respectively. The score r is the relative abundance between type
35 1 and type 2.

1 Definition of EBV amino acid variants

2 Since no gold standard variant set exists for EBV nor any closely related viral species, variant
3 calling was performed using three different variant callers (GATK haplotypcaller, SNVer [47]
4 and VarScan2 [48]) and by selecting as *bona fide* variant set the intersection of the three. The
5 identified EBV variants were annotated using snpEff [49]. Nucleotide variants were
6 transformed into binary amino acid matrices using in-house python scripts. The whole pipeline
7 is written in Snakemake [50] and Python [51].

8 This approach was benchmarked using synthetic libraries generated from B95-8 and AG876
9 using ART Illumina and RNFtools, at a range of coverage between 10X and 250X and 5
10 different admixture conditions, 100% B95-8 or AG876, 75% - 25 % and 50%-50%. Assessing
11 the true number of variants between EBV-1 and EBV-2 strains is not trivial because of the
12 high variability in EBNA-2 and EBNA-3s regions. Therefore, we rated the variant callers and
13 the consensus of the three mentioned callers on self-consistency. The performances of the
14 runs were measured using the ratio of the variant counts to the size of the union of all variants
15 called by a specific tested tool.

16 By using EBV type 2 as a reference, we focused on two types of variation in EBV strains: 1)
17 single amino acid variants; and 2) burden of very rare amino acid variants (present in only 1
18 sample) in each viral gene (Figure 1). We call these datasets *EBV amino acids* and *EBV*
19 *genes*, respectively. Both datasets contain binary values, with a value of 1 standing for "variant
20 present" and 0 for "no variant present". Positions with a coverage of less than 6x were set to
21 "missing" and samples with more than 80% missing positions were excluded entirely. The
22 positions covered by less than 6 reads were considered missing and imputed using the
23 imputePCA function implemented in the missMDA R-package [52]. In total, we obtained 4392
24 amino acid variants and 83 gene variants. However, to limit the risk of model overfitting and
25 because of low statistical power due to sample size we only included in the downstream
26 association analyses the 575 *EBV amino acids* with an amino acid frequency of more than
27 10% and 52 *EBV genes*.

28

29

A. EBV genes and amino acids Example

B. Data Example BNF1 gene

Nucleotides	ID	SNV 1	SNV 2	SNV 3	SNV 4	SNV 5	SNV 6
		1	G	A	G	T	T
	2	G	C	G	T	T	G
	3	G	A	G	T	C	G
	4	G	A	G	T	T	G

Amino acids	ID	Amino acid 1 Glu > Ala	Amino acid 2 Ser > Leu
		1	0
	2	1	0
	3	0	1
	4	0	0

C. Datasets

1 = variant present
0 = no variant present

52 EBV genes

Only aggregates amino acids that appear in one individual.
1 = at least one variant present
0 = no variant present

non-synonymous amino acid variation

Figure 1: Illustration of EBV sequence variation.

A) The EBV genome is about 170 Kbp long and contains 83 genes, for a total of 4392 amino acid residues. As an example, we focus on the *BNRF1* gene and on two amino acid changes: Glu→Ala and Ser→Leu. We know for each sample the genomic variants across the whole genome, as illustrated with the colored nucleotides. Using the nucleotide information and a reference genome we can compute the amino acid changes.

B) We compare each individual (ID) to reference data and encode an amino acid as 1 if that individual has a non-synonymous change, and a 0 if not. This process returns us a matrix containing binary values, with individuals as row, and amino acids as columns. In our example, individual 2 has an amino acid change Glu→Ala and individual 3 an amino acid change Ser→Leu.

C) To transform the data into outcomes for the G2G analysis we can use the amino acid matrix as it is (*EBV amino acids* dataset) or remove all amino acid columns that appear in more than 1 individual and then pool amino acids per gene (1 = variant present, *EBV genes* dataset).

Human genotyping and imputation

A subset of 84 participants had been genotyped in the context of previous studies on several platforms. For the remaining 196 samples, human genomic DNA was isolated from PBMCs with the QIA Symphony DSP DNA Kit (Qiagen, Hilden, Germany), and genotyped using Illumina OmniExpress (v1.1) BeadChip arrays.

1 Genotype imputation was performed on the Sanger imputation server independently for all
2 genotyping platforms, using EAGLE2 [53] for pre-phasing and PBWT [54] with the 1000
3 Genomes Phase 3 reference panel [55]. Low-quality imputed variants were excluded based
4 on imputation INFO score (< 0.8). All datasets were merged, only keeping markers that were
5 genotyped or imputed for all genotyping platforms. SNPs were excluded on the basis of per-
6 individual missingness ($> 3\%$), genotype missingness ($> 1\%$), marked deviation from Hardy-
7 Weinberg equilibrium ($p < 1 \times 10^{-6}$) and minor allele frequency $< 5\%$ (Table 1). All quality control
8 procedures were performed using PLINK 2.0 [56].

9 Association analyses

10 We used the mixed model association implementation for binary and continuous outcomes in
11 GCTA (v1.92) [57,58] to search for potential associations between human SNPs and EBV
12 variants. The model can be expressed with the following equation:

$$13 \quad y_k = \alpha X + \beta^{(kl)} g_l + \eta + \varepsilon$$

14 where the outcome y is a binary vector indicating whether an EBV variant is present (1) or not
15 (0); X is a matrix that contains all covariates, α represents all fixed effects of all covariates
16 (including an intercept term), g is the SNP genotype vector with coded additive allele dosages
17 0, 1 or 2, β is the (fixed) effect of the SNP to be tested for association, η is the polygenic
18 (random) effect and ε the error term. This mixed model was estimated for each EBV variant
19 (k) and SNP (l), and integrated over all L SNPs and K EBV variants. To estimate η , the host
20 genetic relationship matrix (GRM) was calculated from QC preprocessed genotype data using
21 GCTA [57].

22 The use of a mixed effects association model allows to account for population stratification of
23 the host genome. To control for population stratification among EBV genomes, we included
24 the first six principal components (PCs) of EBV genetic variation to the covariate matrix X [59].
25 Other covariates were sex, age and EBV type. PCs were calculated from EBV amino acid
26 variants using the convexLogisticPCA function from the R package logisticPCA [60] in R [61].
27 As data preparation for PC computation, we removed variants with less than 5% or more than
28 95% frequency. Missing amino acid values were imputed with the imputePCA function from
29 the R package missMDA [52].

30 Significance was assessed using the usual genome-wide significance threshold in European
31 populations of 5×10^{-8} and dividing it by the effective number of GWASs performed [62]. We
32 used FINEMAP [63] to determine the most likely causal SNP(s) in a 2-Mb-wide window around
33 each significant SNP. FINEMAP requires GWAS summary statistics and LD estimations as
34 input. To estimate LD between SNPs, we used LDstore [64]. We performed eQTL lookups for
35 host SNPs in eQTLGen [65], EUGENE [66] and GTEx [67].

36 Unless otherwise specified, all data preparation and analyses were performed using R [61].

1 Results

2 Study participants and human genetic data

3 PBMC samples from 778 SHCS participants were screened for the presence of cellular EBV
4 DNA using RT-PCR. A total of 290 of them were identified as viremic for EBV (>2000 copies).
5 We obtained good quality human genotyping and EBV sequencing data for 268 of them, which
6 were included in the association analyses. The study cohort comprised 206 male and 62
7 female individuals, between the ages of 20 and 78 (median 40) (Table 1 and Supplementary
8 Figure S1).

9 We applied standard GWAS quality control (QC) procedures that yielded information for
10 4'291'179 SNPs (Table 1 and Supplementary Figure S2, which shows the distribution of the
11 minor allele frequency spectrum after QC).

12 EBV genomic diversity and variant calling

13 Genome coverage was very uneven between the samples. Mean depth varied from less than
14 6x for 14 samples, up to more than 500x in 5 others. We also observed fluctuation in coverage
15 above 6x, which we used to exclude 12 samples in which less than 20% of the EBV genome
16 was sufficiently covered (Supplementary Figure S7a). In addition, the coverage in the first
17 sequencing batch was not uniform.

18 We estimated the clonality of EBV strain in each sample by taking advantage of the high
19 divergence between EBNA_s T1 and T2 haplotypes. Among the 282 sequenced samples,
20 57.1% were predominantly (9:1) infected by T1 EBV, while 5.7% were mostly infected by T2
21 EBV (Supplementary Figure S6). The remaining 37.2% were infected by multiple strains or by
22 recombinant viruses. This approach does not allow to stratify further than the EBNA types.

23 The variant calling pipeline was adapted to output variants by minimizing the impact of the
24 admixture ratio and of the low coverage observed in the SHCS samples. Variants were called
25 against EBV-2, as EBV-2 was able to call more variants than EBV-1 (Supplementary Figure
26 S7d). The benchmark experiments against AG876 (EBV-2) yielded a total of 961 different
27 variants. The most conservative was SNVer (783 variants), while the most sensitive was
28 BCFtools (930 variants). The variant callers can be prone to artifacts [68], which was
29 specifically observed in SNVer (Supplementary Figure S7c) in these datasets. To reduce the
30 probability of calling artifacts, we chose to use the *bona fide* intersection of GATK HC, SNVer
31 and VarScan2. This approach is likely to be impacted by low coverage. The recall is stable at
32 around 95% at 25X coverage upwards and reasonable (10%) at 20X (Supplementary Figure
33 S7c). Hence, low coverage has an impact, specifically, half potential variants called, on only
34 15% of the SHCS sample. However, this approach is very conservative, since it outputs only
35 88%, 85% and 79% of the variants called by SNVer, GATK HC and VarScan2, respectively.

36 On average, around 800 amino acid variants were called for each sample, with slight
37 differences correlating with the clonality of the samples and the coverage above 6X
38 (Supplementary Figure S7d). The variant counts against the AG876 construct (EBV-2) were
39 generally higher in mixed infections and EBV-1 strains (Supplementary Figure S7d A). The
40 variant counts were generally lower in the samples included in the first sequencing batch,
41 which is likely due to the fluctuating coverage. However, overall, the number of variants was

1 found to be comparable across the samples, ranging from 400 to 1500 for the 77% samples
2 with a 6X coverage above 80% (Supplementary Figure S7d). Under 80% coverage, the variant
3 counts hardly exceed 500 but rarely drops under 200 either. It is therefore likely that we missed
4 variants using our approach. The positions covered by less than 6 reads were considered
5 missing and imputed afterwards using the imputePCA function implemented in the missMDA
6 R-package.

7 We analyzed EBV variation using two approaches: single marker analysis of *EBV amino acids*,
8 *to investigate common viral variation*, and burden testing of very rare amino acid variants in
9 *EBV genes* (Table 1, Supplementary Figure S3). Applying logistic principal component
10 analysis of viral genomic structure showed a single main cluster (Supplementary Figure S4).

11 **Genome-to-Genome association analysis**

12 We tested for associations between each EBV variant and human SNPs. We studied 575 EBV
13 amino acids and 52 EBV genes, for a total of 627 GWASs. The effective number of GWASs
14 performed was 458. As covariates, we included the first six EBV principal components (51.4%
15 deviance explained), sex, age, type 1 vs 2 of EBV (Supplementary Figure S1). The sample
16 size ranged between 120 and 268, with a median sample size of 264. Sample size variation
17 was due to variable missingness in the EBV data. Genomic inflation factors for each of the
18 627 GWASs ranged between 0.92 and 1.12.

19 Significant associations ($p < 1.09 \times 10^{-10}$) were identified between a total of 25 human SNPs
20 and viral variants mapping to three EBV regions (Table 2): the *EBV genes* **BALF5** (Figure 2a)
21 and **BBRF1** (Figure 2b) and the *EBV amino acid* **BRLF1:p.Lys316Glu** (Figure 2c). The minor
22 allele frequency of all significant host SNPs was between 0.05 and 0.10. The genomic inflation
23 factors of the three GWASs ranged between 0.95 and 0.96 (Q-Q plots shown in
24 Supplementary Figure S5).

9 The x-axis represents the chromosomal position and the y-axis displays the $-\log_{10}(p)$.
10 Colour alternates between chromosomes. Regions that contain statistically significant SNP
11 are presented in red (top SNP +/- 400 Kbp). The light grey dashed line represents the GWAS
12 significance threshold of 5×10^{-8} , the dark grey dashed line the G2G threshold of 1.09×10^{-10} .

1 Strong associations were observed between 17 SNPs in the *UNC5D* region on chromosome
2 8 and the occurrence of very rare functional variants in the EBV **BALF5** gene (Figures 2a, 3a),
3 which is involved in viral DNA replication during the late phase of lytic infection. *UNC5D* is a
4 poorly characterized gene expressed mainly in neuronal tissues, which encodes a protein that
5 has been shown to regulate p53-dependent apoptosis in neuroblastoma cells [69]. The top
6 associated SNP, rs2950922 (OR = 1.31, 95%-CI = 1.21-1.41, P = 4.2×10^{-12} , effect allele G),
7 is an eQTL for *UNC5D* in esophageal tissue (GTEx, [67]).

8 Rare amino acid variation in **BBRF1** was found to be associated with a single SNP,
9 rs62124869 (OR = 1.29, 95%-CI = 1.19-1.39, P = 4.2×10^{-11} , effect allele C), which maps to the
10 non-coding RNA gene *LINC01830* (Long Intergenic Non-Protein Coding RNA 1830) on
11 chromosome 2 (Figures 2b, 3b).

12 Finally, 7 SNPs mapping to a non-coding region of chromosome 7 were found to be associated
13 with the EBV amino acid variant **BRLF1:p.Lys316Glu** (Figure 2c, 3c). The top SNP,
14 rs6466720, had a p-value of 6.85×10^{-11} and an OR of 1.41 (95%-CI = 1.28-1.58, effect allele
15 G). **BRLF1** controls lytic reactivation of EBV from latency and regulates viral transcription.
16 **BRLF1:p.Lys316Glu** has not been described previously, but variation at the nearby residue
17 377 (**BRLF1:p.Glu377Ala**) has been shown to be prevalent in cases of nasopharyngeal and
18 gastric carcinomas in Chinese samples [70]. **BRLF1:p.Lys316Glu** and **BRLF1:p.Glu377Ala**
19 are in moderate LD ($r^2=0.55$) in our dataset.

3 **Figure 3:** Locuszoom plots.

4 Locuszoom plots for the three EBV association signals highlighted in red in Figure 2 (A:
5 *BALF5*, B: *BBRF1*, C: *BRLF1*:p.Lys316Glu).

6 Discussion

7 Because immunosuppression - and in particular T cell deficiency - favors EBV reactivation
8 from its latent B cell reservoir, EBV viremia is frequently detected in (untreated) HIV-infected
9 individuals with advanced disease and low CD4+ T cell counts. We hypothesized that the
10 reactivated virus circulating in these patients could carry sequence variants acquired during
11 primary EBV infection, thereby providing a snapshot of early adaptation to the pressure
12 exerted on EBV by the individual immune response.

13 To search for a potential imprint of host genomic variation on the viral sequence, we jointly
14 analyzed genomic information obtained from paired EBV and human samples. Viral sequence

1 variation can be seen as an intermediate phenotype, closer to potentially causal host
2 polymorphisms than clinically observable outcomes like viral load or disease phenotypes. As
3 such, it allows the detection of more subtle associations, less likely to be obscured by
4 environmental influences. In our G2G analysis, we used variation at EBV amino acid residues
5 as outcome in multiple parallel GWAS, which allowed us to obtain effect estimations between
6 each human genetic variant and EBV variation.

7 We identified two EBV genes and one EBV amino acid as associated with three regions of the
8 human genome, spanning altogether 25 SNPs. For the GWAS with **BALF5** as the outcome,
9 the associated human genomic region contains eQTLs for the nearby gene *UNC5D*. This gene
10 is poorly characterized but has been shown to play a role in the regulation of apoptosis [69].
11 The other two EBV genes (**BRLF1**, **BBRF1**) provided little indication of what underlying
12 mechanism might be at play.

13 Our study is limited by its small sample size and by the complexity of correcting for human
14 and EBV population stratification. Indeed, if not carefully controlled for, the existence of
15 population structure in the host and pathogen genome might create spurious associations or
16 decrease real signals in G2G analyses, resulting in both type I and type II errors. With a mixed
17 model approach and the inclusion of pathogen principal components as covariates, the
18 genomic inflation factors of our GWAS ranged between 0.92 and 1.12. This wide range of
19 genomic inflation factors is likely due to a combination of small sample size and complex
20 statistical model. To prevent false positives, we adjusted for genomic inflation when extracting
21 significant SNPs and used a conservative G2G significance threshold of 5×10^{-8} divided by the
22 effective number of GWAS performed. Although viral genetic variation is a more precise
23 phenotype to study than traditional outcomes, it comes at the price of decreased power due
24 to the high-dimensional outcome. The significance threshold is thus much lower than in a
25 single GWAS. To limit the number of statistical tests performed, we restricted our analysis to
26 common gene and amino acid variation.

27 Our analyses have been performed using historical samples collected from untreated HIV-
28 infected individuals. Considering the natural history of EBV infection in humans and its high
29 likelihood to be acquired during the first 2 decades of life, we postulate that intra-host
30 adaptation of EBV happened before HIV infection, i.e. with a normally functioning immune
31 system. At the time of sample collection, all study participants had advanced
32 immunosuppression with low CD4+ T cell counts (< 200 cells/mm³ of blood). We therefore
33 assume an absence of selective pressure on EBV at that time. These assumptions limit
34 obviously the generalizability of our findings to non-HIV-infected population. Similar studies
35 performed during primary EBV infection or in other specific population (e.g. bone-marrow
36 transplant recipients) would help better delineate the global impact of intra-host selection on
37 EBV sequence variation.

38 Our study provides a preliminary list of statistical associations between the EBV and the
39 human genomes. The cataloguing of the sites of host-pathogen genomic conflict is potentially
40 useful for further functional exploration, as has been demonstrated for HIV and HCV infections.
41 Our results require replication and validation in different cohorts and settings. Importantly,
42 larger sample sizes will be needed to increase power and provide more robust estimations.

1 Data availability

2 The datasets generated during and/or analysed during the current study are available in the
3 following Zenodo repositories: G2G results are in <https://doi.org/10.5281/zenodo.4289138>,
4 pathogen data in <https://doi.org/10.5281/zenodo.4011995>.

22 **Acknowledgments**

23 This study was supported by the Leenaards Foundation (Leenaards Prize 2015 to JF and
24 EZ). This study has also been partly financed within the framework of the Swiss HIV Cohort
25 Study, supported by the Swiss National Science Foundation (grant #177499), by SHCS
26 project #743 and by the SHCS research foundation. The data are gathered by the Five
27 Swiss University Hospitals, two Cantonal Hospitals, 15 affiliated hospitals and 36 private
28 physicians (listed in <http://www.shcs.ch/180-health-care-providers>).

29 **Author contributions**

30 EZ and JF conceived and supervised the work.
31 SR and CH performed the association analyses.
32 DPD, SM, JB performed EBV sequencing and curated the data.
33 AL prepared and analysed the viral sequencing data.
34 PJM, DL, ON contributed to the design of the work.
35 SHCS collected the samples and associated data.
36 SR, CH, AL and JF wrote the paper.
37 All authors reviewed the manuscript and approved the submission.

1 Additional information

2 Competing interests

3 CH is an employee of Genentech.

4 Figure legends

5 **Figure 1:** Illustration of EBV sequence variation.

6 A) The EBV genome is about 170 Kbp long and contains 83 genes, for a total of 4392 amino
7 acid residues. As an example, we focus on the *BNRF1* gene and on two amino acid changes:
8 Glu→Ala and Ser→Leu. We know for each sample the genomic variants across the whole
9 genome, as illustrated with the colored nucleotides. Using the nucleotide information and a
10 reference genome we can compute the amino acid changes.

11 B) We compare each individual (ID) to reference data and encode an amino acid as 1 if that
12 individual has a non-synonymous change, and a 0 if not. This process returns us a matrix
13 containing binary values, with individuals as row, and amino acids as columns. In our example,
14 individual 2 has an amino acid change Glu→Ala and individual 3 an amino acid change
15 Ser→Leu.

16 C) To transform the data into outcomes for the G2G analysis we can use the amino acid matrix
17 as it is (*EBV amino acids* dataset) or remove all amino acid columns that appear in more than
18 1 individual and then pool amino acids per gene (1 = variant present, *EBV genes* dataset).

19

20 **Figure 2:** Significant associations - A: *BALF5*, B: *BBRF1*, C: *BRLF1*:p.Lys316Glu.

21 The x-axis represents the chromosomal position and the y-axis displays the $-\log_{10}(\text{p-value})$.
22 Colour alternates between chromosomes. Regions that contain statistically significant SNP
23 are presented in red (top SNP +/- 400 Kbp). The light grey dashed line represents the GWAS
24 significance threshold of 5×10^{-8} , the dark grey dashed line the G2G threshold of 1.09×10^{-10} .

25

Table 1: Summary of pathogen variants, host SNPs and covariates for 268 individuals. For each covariate, we indicate the number of individuals measured, and distribution (mean, median, standard deviation, minimum, maximum for quantitative, frequency for sex). For aggregated EBV genes the frequency is shown, for host SNPs the MAF distribution is presented.

Locus	EBV dataset	EBV outcome	SNP	Chr	OR**	p	Finemapped SNP	Finemapped probability	Effect allele	EAF	n	gene	Consequence type
2	gene (binary, variants < 1 sample)	BALF5	rs2950922*	8	1.30739	4.2E-12	TRUE	0.13317	G	0.10821	268	UNC5D***	intron_variant

1	amino acid (binary)	BRLF1:p.Lys316Glu	rs7808072*	7	1.41346	6.8E-11	FALSE		T	0.06762	244		
1	amino acid (binary)	BRLF1:p.Lys316Glu	rs6466720	7	1.42464	7.7E-11	TRUE	0.04783	G	0.06967	244		

1

2 * SNP with locus-wide lowest P-value

3 ** Odds ratio (exp(b) for logistic mixed effects model) in SHCS

4 *** Gene and tissue of eqtl association (P-value of association), from GTEx:

5 UNC5D in Esophagus_Muscularis (P=1.15243e-13), UNC5D in Esophagus_Gastroesophageal_Junction (P=2.61983e-05)

6

7 **Table 2:** Summary of G2G analysis results. Top SNP and/or fine-mapped SNP per locus represented with: EBV dataset, EBV outcome,
8 chromosome, SNP identifier, odds ratio, p-value, whether this SNP is a top SNP or a fine-mapped SNP, the causal probability from FINEMAP,
9 effect allele, effect allele frequency, sample size, corresponding gene, variant consequence, associated eQTL gene, associated eQTL associated
10 eQTL gene and p-value in GTEx (from <https://gtexportal.org/home/>) [67]. See Supplementary Table S1 for detailed information about all 25
11 variants and Supplementary Table S2 for fine-mapping results.
