11

12 Abstract

13 Objective: Identifying geographic-level prevalence of occupations associated with mobility
14 during local stay-at-home pandemic mandate.

15 Methods: A spatio-temporal ecological framework was applied to determine census-tracts that
16 had significantly higher rates of occupations likely to be deemed essential: food-service, business
17 and finance, healthcare support, and maintenance. Real-time mobility data was used to determine
18 the average daily percent of residents not leaving their place of residence. Spatial regression
19 models were constructed for each occupation proportion among census-tracts within a large
20 urban area.

21 Results: After adjusting for demographics, results indicate census-tracts with higher proportion
22 of food-service workers, healthcare support employees, and office administration staff are likely
23 to have increased mobility.

24 Conclusions: Increased mobility among communities is likely to exacerbate COVID-19
25 mitigation efforts. This increase in mobility was also found associated with specific
26 demographics suggesting it may be occurring among underserved and vulnerable populations.
27 We find that prevalence of essential employment presents itself as a candidate for driving
28 inequity in morbidity and mortality of COVID-19.

Three-question Summary:

- 1) Employees and workers deemed essential during the COVID-19 pandemic are likely to endure additional risk of infection due to community exposure. While preliminary reports are still quantifying this risk, we set out to examine if prevalence of specific occupations could be used to evaluate overall community-level risk based on stay-at-home mandate adherence.
- 2) Study results suggest that that not only are certain occupation geo-spatially associated with movement outside the home but are also associated with demographic characteristics likely to contribute to inequity of COVID-19 morbidity.
- 3) Often, nuanced inequities are lost in the larger data samples, being able to identify possible inequities from other sources such as prevalence of occupation among communities, remains an important and applicable alternative.

56

57 Introduction

58 Inequity in incidence of morbidity and mortality related to the novel coronavirus (COVID-19)
59 has become apparent across U.S. communities. Racial and ethnic minorities are experiencing
60 higher rates of mortality, more rural areas are facing shortages in healthcare resources, and
61 individuals living in poverty continue to present at hospitals in more advanced stages of COVID-
62 19; decreasing the likelihood of positive outcomes.[1-3] Additionally, communities are
63 confronting numerous economic and social challenges brought on by the pandemic; reflected by
64 the nearly 40 million jobs lost, and only a small proportion regained, since the start of the
65 pandemic in the U.S.[4, 5] However, for individuals in frontline employment, or essential
66 occupations, who leave the home for work, inequity and risk of COVID-19 is not yet fully
67 understood. As U.S. mortality reaches over 200,000 as of October 2020, there is a need to
68 identify risk more effectively among vulnerable populations.[6]

69 Throughout the U.S., state and local governments have implemented mitigation mandates to
70 slow the spread of COVID-19.[7] Commonly and with varying degrees of efficacy, these efforts
71 include face-covering requirements, limitations on business capacities, changes to hours of
72 business operations, social-distancing, and recommendations to stay at home.[8] By the nature of
73 viral transmission, staying home remains the most effective COVID-19 prevention method,
74 though it also remains the most challenging for some. Among U.S. states, 42 have published
75 guidelines and mandates of what may constitute an essential worker; an individual employed in
76 an occupation required to be present at a work, largely unable to stay at home. The U.S.
77 Department of Homeland Security defines an essential worker as someone with a range of
78 responsibilities whose continued work is critical to infrastructure operations.[9] Historically, an

79 essential worker has become synonymous with emergency personal: health workers, law
80 enforcement, and those in safety occupations. However, recent research, has shown essential
81 workforce during the COVID-19 pandemic is likely to include transportation workers,
82 employees of restaurants and grocery stores, educators, among other seemingly unrelated
83 occupations.[10] Among these newly-defined essential workers, the burden of community
84 mobility and increased chance of COVID-19 exposure remains unclear both individually and
85 ecologically.

86 Historically, there has been little understood about the impact that community mobility has had
87 on the health of an individual. Previous location-anchored research focused on home or work
88 address, yet the movement throughout an individual's daily lives offers insights, in this case
89 particularly to potential COVID-19 exposure. The purpose of this study was to determine the
90 association among prevalence of occupations and work-related mobility framed within the
91 current COVID-19 pandemic.

92 Materials and Methods

93 This study employed an ecological design with observations at the census-tract level among two
94 densely populated urban Midwest counties (n=305). The study period consisted of all days from
95 March 16, 2020 to May 17, 2020; coinciding with seven days before a stay-at-home mandate for
96 all 1.3 million approximate residents within census-tracts and fifty-six days during the stay at
97 home mandate.

98 Two secondary data sources were utilized for this study. The 2018 5-year American Community
99 Survey (ACS) was used to determine proportion of workers, aged 16 and older, in occupations of
100 interest among each census-tract. These occupations included: 1) healthcare support, 2) food

101 preparation and service, 3) building, ground maintenance 4) management, business, and finance,
102 and 5) office administration support.[11] The ACS was also used to acquire socio-demographic
103 variable per-census-tract that were likely to be associated with adverse health outcome; (1)
104 proportion racial/ethnic minority, (2) proportion earning wages below the federal poverty level,
105 (3) average number of people per household, (4) population density per-square mile, and (5)
106 proportion of residents aged >64.

107 Mobility among census-tracts was estimated using aggregated and anonymized data and acquired
108 as part of a COVID-19 research consortium managed by SafeGraph, LTD, a data management
109 firm. This data was collected using mobile smart device pings collected throughout the day and
110 used to estimate geo-global position. This large dataset contains an estimated 5-10% of the U.S.
111 population. Residency of devices, used to establish proportion of sample leaving home, was
112 calculated by determining the location the device during overnight hours of the day over the
113 course of six weeks.[12] Additionally, this data has been leveraged for similar studies and
114 surveillance, used by state and national organizations.[13]

115 Descriptive statistics were calculated for all variables. A series of Getis-Ord G_i^* cluster analysis
116 were applied among census-tracts for each occupation category to determine locations where
117 they were significantly higher or lower.

118 Each occupational category was used as a primary predictor in a series of multivariate spatial
119 regression models predicting the average proportion of census-tract residents adhering to the
120 stay-at-home order. Each model was adjusted for socio-demographics described a priori as well
121 as the average proportion of census-tract residents staying home seven days before the stay-at-
122 home order as a baseline measurement of mobility. Each model was first constructed under
123 ordinary-least square regression assumptions and a diagnostic cascade was used to detect if

124 spatial dependence was present. Preliminary results indicated that adjusting for this dependency
125 was necessary, thus spatial-lag models were determined to be the best fit.

126 Both descriptive and inferential analyses were completed using R 4.0 and GeoDa 1.14.[14, 15]
127 Significance was determined at α of 0.05 and spatially detected using a pseudo p-value
128 permutation. Spatial weights were applied using a queen contiguity matrix.

129 Results

130 As shown in Table 1, prior to the stay-at-home policy, a daily average of 34.75% +4.92 of the
131 sample did not leave home. During the eight weeks of the stay-at-home policy, a daily average of
132 41.59% +5.51 did not leave home. Average proportions of census-tract residents employed in the
133 occupations of interest included: 15.86% +8.06 working in management, business, and finance,
134 12.37%+4.91 working in office administration support; 6.44% +4.24 working in food
135 preparation and service; 4.25% +4.65 working in healthcare support; and 4.13% +3.68 working
136 in building, ground maintenance.

137 Figure 1 details significant geographical clusters ($p < 0.05$) where each occupation category was
138 higher or lower than dispersion would expect. Among the 305 census-tracts, 50 (16.39%) were
139 identified as having significantly higher proportion of healthcare support workers (Fig 1a); 33
140 (10.81%) as having significantly higher proportion food service and preparation workers (Fig
141 1b); 57 (18.68%) as having significantly higher building, ground maintenance workers (Fig 1c);
142 66 (21.64%) as having significantly higher proportion of business, management, and finance
143 workers (Fig 1d); and 46 (15.08%) identified as clusters with higher proportion of office
144 administration workers (Fig 1e).

145 Table 2 details five spatial regression models, each adjusted for spatial lag, predicting proportion
146 of residents staying home during stay-at-home policy implementation and adjusted for socio-
147 demographics. Model 1 reveals that for every 10% increase in healthcare support workers, the
148 proportion staying home decreases by 1% per-census-tracts ($\beta = -0.1$, $p=0.020$). Similarly, every
149 10% increase in food service and preparation workers results in a 1% decrease in persons staying
150 home (model 2, $\beta = -0.01$, $p=0.019$) Model 5 shows the effects of office administrative workers
151 per census-tract; a 16% increase results in a 1% decrease in persons staying home ($\beta = 0.06$,
152 $p=0.042$). Model 4 displays an opposite pattern; for every 12% increase in proportion of workers
153 in management, business, or finance occupations the proportion of persons staying home
154 increased by 1% ($\beta = 0.08$, $p=0.002$). The occupation category of building, ground maintenance
155 was found not to be a significant spatial predictor of COVID-19 mitigation compliance when
156 adjusting for tract characteristics (model 3).

157 Within regression models, several of the socio-demographic characteristics were determined to
158 be significant predictors of populations staying home. Consistent across all models, as proportion
159 of older adults and population density increased, proportion of census-tract residents staying
160 home also increased. As proportion of those earning income below the poverty level increased,
161 the proportion of tract residents staying home decreased significantly in each model. Average
162 household size and proportion racial/ethnic minorities per-census-tract were also identified as
163 significant model predictors, although inconsistently throughout models.

164 Discussion

165 This study was able to identify relationships among prevalence of occupations and patterns of
166 community mobility that have the potential increase risk for COVID-19 exposure among
167 residents and communities. Areas where census-tract residents were proportionally less likely to

168 remain at home were also likely to have more individuals employed in the fields of healthcare
169 support, food preparation and service, and office administration support. In addition, our study
170 results point to higher proportions of vulnerable populations sharing similar mobility patterns.
171 These types of occupations identified within this study often require fewer credentials, pay
172 substantially less, offer minimal flexibility, and are more likely to be among the limited
173 employment opportunities available to racial and ethnic minorities and residents of low-income
174 communities.[16, 17]

175 These findings highlight the accelerated impact of inequity related to COVID-19. While
176 employment typically serves as a protective factor in many health outcomes, this pandemic has
177 shown that types of employment and the varying context of essential employment change,
178 leaving already vulnerable employees at increased risk for adverse health outcomes. Current
179 literature supports this framework, finding that pandemic essential employment sites require
180 ensuring proper protective equipment, sanitization, and safety protocols, yet, in many cases, are
181 unavailable due the challenges in understanding the transmission and supply chain demands.[18]

182 Community mobility, in this case, provided insights to where and when individuals were home
183 and work during a stay-at-home order. These methods and results highlight the utility of these
184 types of data and how they can provide insights to patterns of behavior and health outcomes
185 throughout communities. Other studies have more widely begun to use these methods and have
186 great opportunity to the growth of our science about how neighborhoods impact our health.

187 {Painter, 2020 #2595 }

188 The pandemic has provided an opportunity for employers, employees, and the public to re-
189 consider such positions now deemed “essential workers.” This will hopefully pave the way for
190 acknowledging and addressing economic inequities that existed prior to the pandemic, but have

191 gained greater visibility, not only in terms of employee safety, but employee value and risk.
192 Efforts such as raising the federal minimum wage and improving the accessibility of healthcare
193 coverage should now be included in conversations highlighting lessons learned from the current
194 pandemic.
