27

28 **ABSTRACT**

29 COVID-19 is one of the largest public health emergencies in modern history. Here we present a
30 detailed analysis from a large population center in Southern California (Orange County,
31 population of 3.2 million) to understand heterogeneity in risks of infection, test positivity, and
32 death. We used a combination of datasets, including a population-representative seroprevalence
33 survey, to assess the true burden of disease as well as COVID-19 testing intensity, test positivity,
34 and mortality. In the first month of the local epidemic, case incidence clustered in high income
35 areas. This pattern quickly shifted, with cases next clustering in much higher rates in the north-
36 central area which has a lower socio-economic status. Since April, a concentration of reported
37 cases, test positivity, testing intensity, and seropositivity in a north-central area persisted. At the
38 individual level, several factors (e.g., age, race/ethnicity, zip codes with low educational
39 attainment) strongly affected risk of seropositivity and death.

51 INTRODUCTION

52 In late 2019 an epidemic of respiratory disease (coronavirus disease 19 or COVID-19),
53 caused by a novel coronavirus (SARS-CoV-2) emerged in Wuhan, China, and rapidly spread
54 worldwide. COVID-19 has manifested in different ways across social, economic, and
55 demographic groups, with regard to apparent risk of infection, disease severity, and mortality (1–
56 3). The elderly and those with co-morbidities are at the highest risk of severe disease (4). Many
57 hospitalized patients require supplemental oxygen or ventilators (5), and there is a high mortality
58 rate among those who are hospitalized (6). In many places healthcare facilities have been
59 overwhelmed by a surge in cases and have fallen short of needed ventilators and ICU beds,
60 resulting in massive morbidity and mortality(7,8). Availability of tests and operational barriers
61 were limiting factors for diagnosis in parts of the U.S. during the early months of the pandemic
62 (9).

63 California is the most populous state in the U.S., with an estimated 39.5 million
64 inhabitants. Orange County (OC) is a coastal county in California, and the sixth most populous
65 county in the country, with an estimated 3.2 million inhabitants). The first confirmed case in
66 California (3rd in the U.S.) was reported from OC. On January 31 the WHO declared a Global
67 Health Emergency, and on February 3rd the U.S. declared a public health emergency. Subsequent
68 cases were reported in California in February, mostly among travelers. On February 26th, local
69 ('community') transmission was first confirmed in the United States in northern California. OC
70 had only 2 reported cases in February. By March 11 another 6 cases had been reported in OC. On
71 March 12 there were 8 reported cases; followed by 23 on March 13; 11 each day on March 14
72 and 15; and 32 on March 16. This surge in cases in mid-March in OC and other counties in
73 California triggered emergency orders by the Governor and the County Health Officer at the

74 Orange County Health Care Agency, prohibiting public or private gatherings and also leading to
75 school and business closures (10). Though many businesses were closed at this time, the
76 mandated social distancing measures had exceptions in place for individuals working in
77 “essential jobs,” which was broadly defined and included medical professionals, food providers,
78 delivery agencies, public officials, contractors, and building laborers (11). The social and
79 economic characteristics of individuals working essential jobs likely differs from the overall
80 population.

81 Almost half of OC residents over the age of five speak a language other than English at
82 home. Additionally, many within the Hispanic/Latino and Asian communities of OC live below
83 the poverty level (17.9% and 16%, respectively) and face challenges in education, household
84 income, access to healthcare, health disparities, and life expectancy (12,13). The relatively small
85 land area, high population density, and diverse population of OC provides a unique opportunity
86 to explore potentially important social, economic, and demographic correlates of COVID-19
87 epidemiology.

88 Here we present results from a detailed spatiotemporal epidemiological analysis of
89 COVID-19 in OC, California. First, we draw from reported tests and mortality from the county
90 health agency. Given that passively detected cases are prone toward bias, in July we also
91 conducted a seroprevalence survey to assess the true burden of disease in the county. In our
92 analyses we leverage both datasets to compare predictors of test positivity, mortality, and
93 seropositivity over the first 6 months of the epidemic.

94

95 **METHODS**

96 *Data.*

97 Case and Mortality data.

98 Case data were provided through a memorandum of understanding with the Orange
99 County Health Care Agency (OCHCA) and consisted of individual level records of all negative
100 and positive PCR tests conducted throughout the county from March 1 through August 16, 2020
101 (this date aligns with our cross-sectional seroprevalence survey which completed on August 16).
102 OCHCA receives testing data from the California Reportable Disease Information Exchange
103 (CalREDIE), an infectious disease surveillance system implemented by the California
104 Department of Public Health (CDPH) [14]. The data include information on test date, age,
105 gender, race, ethnicity, and zip code of the individual taking the test. For individuals who had
106 repeat PCR testing after testing positive, only the first positive diagnosis was included in our
107 analyses. Mortality data were also provided by OCHCA and consisted of individual-level records
108 of deaths attributed to COVID-19.

109

110 Seroprevalence data.

111 Participants for the serological survey were recruited using a proprietary database
112 maintained by SoapBoxSample, an LRW Group Company. The database is intended to be
113 representative of the age, income, and racial/ethnic diversity of OC. Participants were contacted
114 by email or phone. We recruited one participant per household to participate in a survey on their
115 thoughts and opinions regarding COVID-19. The survey included questions on socio-
116 demographics, occupation, social activities, any illness or symptoms in the last few months, and
117 whether the individual had been diagnosed with COVID-19. After completing this portion of the
118 survey, each eligible participant was asked if they would be willing to participate in a drive-thru
119 blood test for SARS-CoV-2 antibodies. Eligibility for antibody testing was restricted to a quota

120 sample designed to be demographically representative of the county as a whole. Recruitment to
121 the antibody test was delayed to the end of the questionnaire in order to avoid biasing the
122 serological survey toward individuals who believe that they were infected with SARS-CoV-2.
123 There were a total of 10 field sites for drive-through blood tests, dispersed throughout OC in
124 order to minimize driving distances for participants. The seroprevalence study design and overall
125 findings for OC are described in more detail elsewhere (14).

126

127 Serological test.

128 We used a coronavirus antigen microarray to classify participants from the serological
129 survey as seropositive or seronegative. The array tests for both IgG and IgM and contains 12
130 antigens from SARS-CoV-2 (described in detail at (15)).

131

132 Zip-code level socio-demographic data.

133 At the zip-code level we included median household income, the percentage of adults
134 above age 25 who have at least a bachelor's degree, and the percentage of adults who have had
135 insurance in the previous 5 years. These data come from the 2018 American Community Survey
136 of 2018 (extracted from (12)).

137

138 *Analysis.*

139 Descriptive Spatiotemporal Data Analysis.

140 Reported cases and number of tests were aggregated at the zip code level and by week. A
141 total of 85 zip codes were included in the analysis. For plotting cases on OC maps, the data were
142 further aggregated by months (March through August). Case incidence was calculated and

143 mapped as positive cases per 100,000 population per week. Testing intensity was calculated and
144 mapped as total number of tests per 100,000 people per week. Test positivity was calculated and
145 mapped as the percentage of positive tests for each month.

146 Formal testing of spatial autocorrelation was done using the global Moran's *I* statistic and
147 spatial correlograms. Both identify the presence and extent of clustering or dispersion. Local
148 clustering statistics (Local Indicators of Spatial Autocorrelation or LISA (16)) were then used to
149 visualize the location of clusters. All tests were run for case incidence, test positivity, and test
150 intensity. Seropositivity was also mapped and assessed using LISA statistics (since this was a
151 cross sectional survey there is no time component).

152

153 Relational Analysis of COVID-19 Test Positivity, Mortality, and Seropositivity.

154 We used logistic regressions to explore geographic, demographic, economic, and
155 epidemiological predictors of the odds of testing positive for COVID-19, of dying from COVID-
156 19, and of being seropositive for SARS-CoV-2 antibodies. Predictors in our models are listed in
157 **Supplementary Table 1** and included: age group, gender, and race/ethnicity at the individual
158 level. Zip code level predictors included: median household income, the percentage of adults
159 over age 25 with at least a bachelor's degree, the percentage of adults who have had insurance in
160 the previous 5 years, and population density (individuals per square kilometer).

161 Several specifications were tested for model fit, interpretability, and parsimony. Through
162 preliminary exploratory analyses we noted that the first cases were reported from coastal zip-
163 codes but that this pattern had shifted inland over time. Given the changing dynamics over time,
164 we explored different specifications for 'time' in the model for test positivity. The best fitting

165 model included a smoothed interaction term for time (coded by day, **Supplemental Table 1**) and
166 median household income at the zip code level.

167 The same predictors were included in the model for mortality, save for the interaction
168 between time and median household income (which did not improve model performance). Given
169 reports of increased mortality related to hospital bed shortages, we also included as a predictor
170 the number of ICU beds occupied by suspected or confirmed COVID-19 patients on the day that
171 an individual tested positive for SARS-CoV-2.

172 We compared three seropositivity models, with various combinations of individual and
173 zip-code level predictors (see details in **Supplementary Appendix A**). All model results are
174 presented as model adjusted odds ratios (AORs) with 95% confidence intervals (CIs). Model
175 summary statistics, including model Bayesian Information Criterion are presented in
176 **Supplementary Appendix A**.

177

178 *Software.*

179 Maps were created using QGIS version 3.4.9. Tests for spatial autocorrelation were done
180 using GeoDa version 1.14.0. All other analyses were conducted using R statistical software
181 version 3.5.2.

182

183 **RESULTS**

184 A total of 597,922 tests were reported to OCHCA up to August 16, 2020. After dropping
185 repeated tests and those with incomplete data, 318,492 individuals were included. Of these
186 individuals, 36,816 tested positive for COVID-19 and 1,248 died from the disease. In the

187 separate population-based serological survey, 2,979 individuals participated and 350 tested
188 seropositive.

189

190 *Spatial patterns in reported COVID-19 cases, testing intensity, and seropositivity*

191 The global Moran's I statistics and spatial correlograms indicated significant clustering in
192 reported cases and testing intensity in the first month (March) of the local epidemic (**Table 1;**
193 **Supplementary Figures 3 and 4**). Conversely, there was no detectable clustering of test
194 positivity in March (**Table 1, Supplementary Figure 5**). The highest reported case incidence in
195 March was along the central coast and southern portion of the county (**Figure 1 A**). The LISA
196 statistics indicated statistically significant clustering of high incidence zip codes in the central
197 coast area (**Figure 1 B**). This clustering of case incidence overlaps with clustering of test
198 intensity in March (**Figure 2 A and B**).

199 Clustering of both reported cases and test positivity increased in magnitude in May
200 (**Table 1 and Supplementary Figures 3 and 5**). While clustering in test intensity (**Table 1;**
201 **Supplemental Figure 4**) was high in March, it decreased in May as access to testing spread
202 throughout much of the county. Clustering in testing intensity increased again in June and July
203 (centered on the hotspots in the north-central part of the county, evident in **Figures 1 and 3**). By
204 April, case incidence, testing intensity, and test positivity had all shifted to a growing cluster in
205 the north-central part of the county. Zip code level seropositivity also revealed a cluster in the
206 north-central part of OC (**Figure 4**), especially in the city of Santa Ana (**Supplementary Figure**
207 **1**).

208

209 *Results from GAM Logistic Regressions*

210 Factors associated with testing positive for SARS-CoV-2 infection

211 Age was a strong predictor of testing positive. Individuals in the 10-14 and 15-19 age
212 groups had the highest odds of testing positive (both with approximately 2.2 times the odds of
213 testing positive in comparison to the 0 – 4 age group (**Table 2** and **Figure 5**)). Males had 1.2
214 times the odds of testing positive (95% CI: 1.18 – 1.23). Individuals who identified as Hispanic
215 or Latino had 1.7 times the odds of testing positive (CI: 1.63 – 1.79) when compared to whites,
216 while Asian (AOR: 0.52; CI: 0.49 – 0.55), Black (AOR: 0.58; CI: 0.52 – 0.66), and Pacific
217 Islander (AOR: 0.35; CI: 0.29 – 0.42) individuals had lower odds of testing positive. A large
218 proportion of individuals did not have attributable race or ethnicity data in the records (63 % of
219 all records through August 16).

220 Zip code level population density was not a significant predictor of testing positive
221 (**Table 2, Figure 5**). However, education (percentage of adults with at least a bachelor's degree),
222 insurance coverage (percentage of adults who had insurance in the previous 5 years), and median
223 household income were all statistically significant predictors of testing positive. For example,
224 individuals who lived in zip codes with the highest education levels had 39% decreased odds of
225 testing positive (AOR for the fourth quartile: 0.61; CI: 0.49 – 0.76). In addition, the interaction
226 between zip code level median household income (**Supplementary Figure 2**) indicates that
227 individuals from wealthier zip codes had increased risk of testing positive at the beginning of the
228 OC epidemic. However, this pattern quickly shifted, with individuals from lower income areas
229 showing the highest odds of testing positive in subsequent months.

230

231 Factors associated with COVID-19 associated mortality

232 For each increase in 10 years of age there was an associated 2.5 fold increase in the odds
233 of mortality (AOR: 2.56, CI: 2.46 – 2.67; **Table 3, Figure 6**). Infected males were almost twice
234 as likely to die from COVID-19 when compared to females (AOR: 1.97; CI: 1.71 – 2.26). While
235 Asian individuals were less likely to test positive for SARS-CoV-2 infection (**Table 2**), those
236 who did test positive had higher odds of mortality. Compared to whites, Asians had 31%
237 increased odds of dying from COVID-19 (AOR: 1.31; CI: 1.08 – 1.59).

238 Living in zip codes with high education levels and insurance coverage was also
239 predictive of mortality outcomes (**Table 3, Figure 6**). Individuals who tested positive for
240 COVID-19 and lived in zip codes with the highest levels of educational attainment had 45%
241 lower odds of dying (AOR for the fourth quartile: 0.55; CI: 0.34 – 0.89). Those who lived in zip
242 codes with the highest levels of insurance coverage had 41% lower odds of dying. Zip code level
243 population density and median household income were not significant predictors of mortality
244 after accounting for the other risk factors.

245 There was no significant change in risk of COVID-19 mortality over this time period.
246 The number of COVID-19 patients in ICU was also not predictive of mortality.

247

248 Factors associated with SARS-CoV-2 seropositivity

249 Zip code level cumulative incidence was a significant predictor of individual-level
250 seropositivity in the absence of other zip code level predictors (**Supplementary Table 2**). Every
251 increase in 10% of the zip code cumulative incidence resulted in approximately a 50% increase
252 in the odds that an individual would be seropositive.

253 Zip code level cumulative incidence was no longer a statistically significant predictor of
254 seropositivity when other zip code level predictors were added to the model (**Table 4, Figure 7**).

255 In the full model (including all zip code level covariates) median household income had a
256 protective effect, with individuals coming from zip codes with higher median household income
257 having lower odds of being seropositive for SARS-CoV-2 antibodies (AOR for every one
258 standard deviation increase: 0.75; CI: 0.57 – 0.98).

259 We found no difference in age groups with regard to seropositivity. While males were
260 more likely to test positive or to die from SARS-CoV-2 infection, they were less likely than
261 females to be seropositive (AOR: 0.75; CI: 0.59 – 0.94). Hispanic and Latino individuals had
262 55% increased odds of being seropositive (AOR: 1.55, CI: 1.17 – 2.03). Pacific Islanders may
263 also have had higher odds of being seropositive, but with small total numbers and broad
264 confidence intervals (AOR: 3.94, CI: 1.07 – 14.57; a total of 3 out of 12 individuals tested were
265 seropositive).

266

267 **DISCUSSION**

268 Infectious disease data from passive case detection can be biased in a variety of ways,
269 including the well-documented challenge of uneven access to testing and diagnosis (17). In our
270 analysis of COVID-19 in OC, we used a rich set of complementary data that include those
271 passively collected (reported cases, mortality records) and those from active screening
272 (population-based serological testing). Results indicate that, in the early days of the epidemic in
273 OC, both testing intensity and test positivity concentrated in wealthy and affluent areas along the
274 central coast. After March, however, a large cluster of reported cases formed in lower-income
275 North-Central OC (especially the cities of Santa Ana and Anaheim, **Supplementary Figure 1**),
276 growing in size in May and persisting over time. Testing intensity has spread throughout the
277 county during this same time period.

278 Consistent with emerging reports, we also found that age and male gender strongly
279 predict testing positive and COVID-19 associated mortality (18). Intriguingly, whereas older age
280 groups and males were more likely to have symptomatic disease, our population-based
281 serological survey found that females were more likely than males to be seropositive. Hispanic
282 and Latino individuals had higher risk of infection and testing positive, even after controlling for
283 several zip code level socio-economic factors. Given the consistency of this racial/ethnic finding
284 between the models for test positivity and seropositivity, the risk of being infected with SARS-
285 CoV-2 rises above and beyond the risks of living in a zip code with high transmission or a zip
286 code with low-income and low levels of educational attainment. Other studies also note an
287 increased risk of testing positive for Hispanics and Latinos (19–21). Our seroprevalence survey
288 indicates that in OC, this finding is not an artifact of passive case detection but instead represents
289 a true greater risk of infection for Hispanics and Latinos.

290 While Asians were less likely to test positive for COVID-19, they were more likely to die
291 when infected. This disparity is consistent with national data, though its cause is uncertain (22).
292 This pattern may reflect discrepancies in outreach communication to these communities or other
293 socio-economic and cultural factors (23,24) and warrants further detailed investigation.

294 Social determinants of health, defined as "conditions in which people are born, grow,
295 work, live, age, and the wider set of forces and systems," play a critical role in the creation of
296 disparities related to morbidity, mortality, and quality of life (25). These social determinants
297 include (among other factors) poverty, wealth, educational quality, neighborhood conditions,
298 childhood experience, and social support. Several speculative explanations have been proposed
299 for these sociodemographic patterns related to COVID-19, including living in dense quarters. In
300 addition, as the state and local shelter in place and social distancing policies were mandated,

301 individuals who are independently wealthy or who work in occupations where working from
302 home is a viable option, were more capable of practicing social (more accurately “physical”)
303 distancing. People from low socioeconomic status (SES) areas, by contrast, may have less ability
304 to practice social distancing. Our analyses show that individuals from zip codes with lower
305 overall educational attainment and insurance coverage were more likely to test positive for and
306 die from COVID-19. The association with median household income was more complex and
307 changed over time with regard to test positivity. However, we also find that individuals from zip
308 codes with lower median household income were also more likely to be seropositive for SARS-
309 CoV-2. These findings underscore the importance of understanding contextual factors
310 surrounding infectious disease outbreaks.

311 Study limitations include that County-reported testing and mortality data did not include
312 individual-level information on income, education, and insurance. These variables were only
313 available at the zip code level. Zip codes are unlikely to adequately represent important spatial
314 units (e.g., neighborhoods, communities). Our measure of population density may also not
315 accurately capture the importance of housing or household density. Missing data on
316 race/ethnicity (63% of all official test records) and small counts of some race/ethnicity groups
317 may have impacted our findings for groups with low counts in this analysis. Even when
318 race/ethnicity data were available, they were broad categories (i.e. Asian rather than specific
319 Asian ethnicities). We also note, however, that the population-based seroprevalence data on
320 SARS-CoV-2 included detailed individual-level information on socio-demographic covariates,
321 which we exploited for our detailed analyses.

322 Study strengths include the diversity of OC in terms of socioeconomic and demographic
323 predictors, which provide sufficient power to investigate these factors in our analyses. California

324 was also one of the first states to issue an executive order for residents to stay home, providing
325 data for several months when only essential workers were permitted to work outside the home.
326 Our analyses were able to identify temporal shifts in the demographics of COVID-19 test
327 positivity that likely reflect disparities related to occupation type that are further amplified by
328 household characteristics. Finally, we are able to assess differences in risk of infection and test
329 positivity by comparing our population-level serological survey to routinely collected (passive)
330 data from County statistics.

331 The reasons for the spatial, socio-demographic, and economic patterns we discovered are
332 likely complex and broadly related to issues of accessing health care and general social
333 determinants of health. The clear disparities in how this disease has manifested in OC point
334 toward the need for approaches that are socio-culturally appropriate and those that have a focus
335 on health equity as a fundamental building block. Measures that focus on the hardest-hit
336 communities may serve as efficient points of intervention for COVID-19.

337

338 **ACKNOWLEDGEMENTS**

339 We acknowledge the actOC research manager (Emily Drum) and logistical expertise of
340 Dr Bruce Albala for setting up and helping run the seroprevalence study. Many UCI students and
341 alumni were involved in collecting blood samples for the serological survey and we gratefully
342 acknowledge their contributions. We are grateful to the Felgner lab members who made the
343 serological survey possible under sometimes trying conditions (especially Rie Nakajima, Aarti
344 Jain, and Rafael Ramiro de Assis). Guiyun Yan and Xiaoming Wang provided space for cold
345 storage. The serological survey was funded through a contract with OCHCA (MA-042-
346 20011978). We also acknowledge conversations with colleagues and community leaders with

347 regard to social determinants of health and health equity, including but not limited to: Sora
348 Tanjasiri, Mary Anne Foo, Brittany Morey, Ahn Ellen, Tricia Nguyen, America Bracho, and
349 many others.

350 **First author biography**

351 Dr. Parker is an infectious disease epidemiologist with expertise in spatial epidemiology,
352 demography, and biomedical anthropology. He is an assistant professor in public health at the
353 University of California, Irvine and the director of the Global Health Research, Education, and
354 Translation (GHREAT) initiative.

447 **Table 1.** Global Moran's *I* statistics for reported case incidence, test positivity, and testing intensity for
448 each month of the study period (March – August). The *I* statistic indicates the degree of spatial
449 clustering whereas the simulated p-value gives an indication of statistical significance. Moran's *I* values
450 roughly range from -1 to 1, with 1 indicating complete spatial clustering (i.e. all areas with high values
451 are neighboring other areas with high values) and -1 indicating complete spatial dispersion (with high
452 value areas always neighboring low value areas).
