56

57 **Abstract**

58 Central obesity is a leading health concern with a great burden carried by ethnic minority populations,
59 and especially Hispanics/Latinos. Genetic factors contribute to the obesity burden overall and to inter-
60 population differences. We aim to: 1) identify novel loci associated with central adiposity measured as
61 waist-to-hip ratio (WHR), waist circumference (WC), and hip circumference (HIP), all adjusted for body
62 mass index (adjBMI), using the Hispanic Community Health Study/Study of Latinos (HCHS/SOL); 2)
63 determine if differences in genetic associations differ by background group within HCHS/SOL; 3)
64 determine whether previously reported association regions generalize to HCHS/SOL. Our analyses
65 included 7,472 women and 5,200 men of mainland (Mexican, Central and South American) and
66 Caribbean (Puerto Rican, Cuban, and Dominican) background residing in the US, with genome-wide
67 array data imputed to the 1000 genomes Phase I multiethnic reference panel. We analyzed associations
68 stratified by sex in addition to sexes combined using linear mixed-model regression. We identified 16
69 variants for WHRadjBMI, 22 for WCadjBMI, and 28 for HIPadjBMI that reached suggestive significance
70 ($P < 1 \times 10^{-6}$). Many of the loci exhibited differences in strength of associations by ethnic background and
71 sex. We brought a total of 66 variants forward for validation in nine cohort studies (N=34,161) with
72 participants of Hispanic/Latino, African and European descent. We confirmed four novel loci (ancestry-
73 specific $P < 0.05$ in replication, consistent direction of effect with HCHS/SOL, and $P < 5 \times 10^{-8}$ after meta-
74 analysis with HCHS/SOL), including rs13301996 in the sexes-combined analysis, and rs79478137 for
75 women-only for WHRadjBMI; rs28692724 in women-only for HIPadjBMI; and rs3168072 in the sexes
76 combined analysis for WCadjBMI. Also, a total of eight previously reported WHRadjBMI association
77 regions, 12 for HIPadjBMI, and 10 for WCadjBMI generalized to HCHS/SOL. Our study findings highlight
78 the importance of large-scale genomic studies in ancestrally diverse Hispanic/Latino populations for
79 identifying and characterizing central obesity-susceptibility that may be ancestry-specific.

80 Introduction

81

82 Obesity, and especially central obesity, is a leading risk factor for metabolic and cardiovascular
83 diseases, with the greatest burden carried by minority populations (1-4), particularly Hispanic/Latino
84 Americans and African Americans (5). Emerging evidence suggests that genetic factors may contribute
85 not only to the obesity burden overall, explaining 40% to 70% of the inter-individual variation (6), but
86 also to population-specific differences in obesity susceptibility (7-12). For example, although a majority
87 of the >1000 genome-wide association study (GWAS)-identified obesity (body mass index (BMI), waist-
88 to-hip ratio (WHR), waist circumference (WC), hip circumference (HIP), and body fat percentage) loci
89 generalize across populations (13-20), recent studies in populations of Asian (19, 20) and African (16, 21)
90 ancestry have revealed a number of novel and population-specific loci. These observations highlight the
91 importance of large-scale genomic studies in ancestrally diverse populations, including Hispanic/Latinos,
92 to identify obesity-susceptibility loci, and more specifically, alleles that are ancestry-specific and may
93 thus partly explain disparities. However, no large-scale GWAS for any obesity-related traits has been
94 performed in Hispanic/Latino populations, despite their increased prevalence of obesity.

95 While obesity is commonly assessed by BMI, measures of central adiposity such as WHR and WC
96 are predictors of increased cardiometabolic risk independent of BMI (22-25). Here we consider three
97 measures of central obesity: WHR, WC, and HIP after accounting for overall body size, measured as body
98 mass index (BMI) (WHRadjBMI, WCadjBMI, HIPadjBMI). Larger WHR indicates increased abdominal fat
99 and is associated with increased risk for type 2 diabetes (T2D) and cardiovascular disease (CVD) (26-28),
100 while smaller WHR indicates a proportionately greater fat accumulation around the hips, and is
101 associated with lower risk for T2D, hypertension and dyslipidemia (29). Previous GWAS have identified
102 WHR, WC, and HIP loci that are enriched for association with other cardiometabolic traits and suggested
103 that different fat distribution patterns can have distinct genetic underpinnings (30-32). Identifying

104 genetic risk variants across these traits in Hispanic/Latinos may provide insights into these mechanisms
105 and highlight population-specific variants that increase susceptibility to obesity in specific groups.

106 We aimed to: 1) identify novel genetic loci associated with central obesity, measured here as
107 WHRadjBMI, WCadjBMI, and HIPadjBMI, in Hispanics/Latinos; 2) determine if differences in genetic
108 associations by background group (mainland or Caribbean) and sex exist in HCHS/SOL; and 3) assess
109 generalization of central adiposity associated loci discovered in European, African and multi-ethnic
110 studies to Hispanics/Latinos.

111

112 **Results**

113

114 **Discovery**

115 We identified 16 loci for WHRadjBMI, 22 for WCadjBMI, and 28 for HIPadjBMI that exhibited
116 suggestive evidence of association in the HCHS/SOL in at least one stratum (**Table 1, Figures 1-3,**
117 **Supplementary Tables 2-4, Supplementary Figures 1-12**). For WHRadjBMI, we identified four loci that
118 reach suggestive significance ($P < 1 \times 10^{-6}$) in the combined sexes, including rs12435790 near *KIAA0391*,
119 which is within a previously reported WHRadjBMI locus (+/- 500 Kb from tag SNP) (33). We also
120 identified five loci for men only, including one reaching genome-wide significance (GWS, $P < 5 \times 10^{-8}$). A
121 total of eight suggestive loci were identified in the women-only analyses, including one, rs115981023 in
122 *TAOK3*, which also reached suggestive significance in the combined sexes analysis, and rs79478137 in
123 *SLC22A18AS* near a previously implicated WHRadjBMI locus(34). For WCadjBMI, we identified nine loci,
124 including one GWS locus in the combined sexes; 11 for men only, including two SNPs that reach GWS;
125 and two for women only. Of the WCadjBMI loci identified, two were nearby previously-reported
126 WCadjBMI loci, rs6809759 near *PROK2* (men-only) (15, 17, 35) and rs77319470 near *ADAMTS3* (sexes-
127 combined) (15, 17, 36). For HIPadjBMI, we identified eight loci that reach $p < 1 \times 10^{-6}$ for the combined

128 sexes; nine for men only, including one in a locus that reached suggestive significance for the combined
129 sexes as well (near *ANO10*); and 12 for women only, including one SNP in a locus that reached
130 suggestive significance for the combined sexes as well (near *LPPR4*). Of the WCadjBMI loci, rs10818474
131 near *MEGF9* was within 500 Kb of a recently reported WHRadjBMI association in women (35).

132

133 **Association Differences by Genetic Ancestry**

134 All of the top loci were directionally consistent in each background group, yet many of the loci
135 exhibited effect heterogeneity by background group (**Table 2, Figures 1-3, Supplementary Tables 5-7**),
136 as exhibited by moderate to high I^2 values ($ISQ>65\%$) and/or significant interaction across subgroups
137 ($P_{diff}<0.05$). For example, rs113818604 ($\beta=0.0269$, $P=5.47 \times 10^{-8}$), $I^2=78.5\%$, $P_{diff}=0.38$) in *NTM* is
138 significantly associated with WHRadjBMI in women from the mainland background groups (N=4220,
139 MAF=0.014, $\beta=0.0343$, $P=1.63 \times 10^{-8}$), but not in women from Caribbean background groups (N=3238,
140 MAF=0.013, $\beta=0.0144$, $P=0.08$) (**Supplementary Table 5**). Also, for the women-only primary analysis, the
141 rs77186623 in *LOC105375745* locus associated with HIPadjBMI ($\beta=-0.006$, $P=1.74 \times 10^{-7}$) exhibited
142 nominally significant interaction by background group ($I^2=55.3\%$, $P_{diff}=0.042$), and was GWS in the
143 Caribbean group (N=3231, MAF=0.041, $\beta=-0.0078$, $P=3.05 \times 10^{-8}$), but not significant in the mainland
144 group (N=4216, MAF=0.008, $\beta=-0.0015$, $P=0.567$, **Supplementary Table 7**). Additional examples that
145 cannot be explained due to power (i.e. MAF and sample size are similar) for WHRadjBMI include
146 rs77377042 near *MARCKSL1* and rs61305557 in *C19orf67* for women, and rs16977373 near *RIT2* for
147 men; for WCadjBMI in women-only include rs76842062 in *MAP4K4* and rs76941364 near *COBL*; and for
148 HIPadjBMI rs6860625 near *NREP* for women and rs145815581 in *ANO10* for the combined sexes.

149 For other loci, allele frequency and linkage disequilibrium (LD) differences across
150 Hispanic/Latino populations likely contributed to observed differences in magnitude of effect and
151 significance levels (**Supplementary Table 8**). For example, while the magnitude of effect for the

152 rs115981023 *TAOK3* association with WHRadjBMI in women ($\beta=-0.029$, $P=8.88 \times 10^{-7}$, $I^2=0$, $P_{diff}=0.391$)
153 was similar across background groups, the P-value was far more significant in the Caribbean background
154 group (MAF=0.016, $\beta=-0.030$, $P=2.72 \times 10^{-5}$) compared to the mainland (MAF=0.003, $\beta=-0.027$, $P=0.025$),
155 likely due to the higher MAF in the Caribbean group. Of note, the minor allele at this SNP is more
156 common in the 1000 Genomes AFR compared to the EUR and AMR reference samples (**Supplementary**
157 **Table 5**) and the local ancestry of participants at this locus indicate that those with African ancestry
158 exhibit the highest MAF (**Supplementary Table 8**). Additional loci where the significance level
159 differences between Caribbean and mainland background groups appear to be driven by increased MAF
160 due to African ancestry in Caribbean populations include the *SLC22A18AS* and *CDH4* loci for
161 WHRadjBMI; *LOC102723448*, *FZD7*, *WSB2*, and *ACTRT2* loci for WCadjBMI; and *COQ2*, *LPPR4*, *TMEM63A*,
162 and *FHIT* loci for HIPadjBMI (**Supplementary Tables 5-8**). Rs12478843 in *HEATR5B* ($\beta=-0.002$, $P=8.2 \times 10^{-8}$,
163 $I^2=1.7\%$, $P_{diff}=0.385$) is more significantly associated with HIPadjBMI in mainland (MAF=0.320, $\beta=-0.002$,
164 $P=6.50 \times 10^{-6}$) women compared to Caribbean (MAF=0.154, $\beta=-0.002$, $P=6.03 \times 10^{-3}$), likely reflecting the
165 higher MAF among those from mainland Latin America with greater Native American ancestry
166 (**Supplementary Table 8**). Similarly, differences in effect magnitude between mainland and Caribbean
167 background groups for the *TAF4* (HIPadjBMI in women) and the *ESRRG* (WCadjBMI in men) loci may also
168 be due to higher MAF in the mainland group because of a greater proportion of Native American
169 ancestry (**Supplementary Tables 6-8**).

170

171 **Replication**

172 We brought 66 variants forward for replication in nine cohort studies (N up to 34,161) with
173 participants of Hispanic/Latino, African and European descent, and for further examination of
174 replication by ancestral background (**Table 1**, **Supplementary Tables 1-4**, **Supplementary Figures 10-12**).
175 Our criteria for replication included both nominal evidence of an association ($P<0.05$), consistent

176 direction of effect between the replication results and the HCHS/SOL discovery results for any
177 ancestry/sex stratum, and genome-wide significance ($P < 5 \times 10^{-8}$) when meta-analyzed together with
178 HCHS/SOL. Based on these criteria, we were able to replicate four novel loci (**Table 1**) after combining
179 our HCHS/SOL discovery sample with specific ancestry results. For WHRadjBMI in men and women
180 combined, rs13301996 was significant after meta-analyzing HCHS/SOL with the African American
181 replication sample ($P = 2.88 \times 10^{-8}$). For WHRadjBMI in women only, rs79478137 was GWS after combining
182 HCHS/SOL with the Hispanic/Latino replication sample ($P = 3.64 \times 10^{-9}$). For HIPadjBMI in women only,
183 rs28692724 was significant after meta-analyzing HCHS/SOL with the European American replication
184 sample ($P = 4.02 \times 10^{-8}$). For WCadjBMI in men and women combined, rs3168072 was significant after
185 combining HCHS/SOL with the European American replication sample ($P = 4.21 \times 10^{-8}$).

186 Of note, for rs13301996, which only replicated in African Americans, we see a larger effect size
187 in the Caribbean background group compared to the mainland, although this is not a significant
188 difference (**Table 2, Supplementary Table 5 Supplementary Figure 10**). This finding may provide insight
189 into why the variants were more successful upon replication with a particular ancestry. For the
190 remaining loci there is little difference in effect magnitude between the Caribbean and the mainland
191 background groups that could explain differences in replication by ancestral group.

192 **Generalization of Previous Loci**

193 We examined previously reported association regions from the GIANT Consortium (35) to assess
194 generalization to the HCHS/SOL (**Supplementary Tables 9-11, Supplementary Figures 13-21**). To account
195 for differences in LD between GIANT (primarily European descent populations) and HCHS/SOL (highly
196 admixed Hispanic/Latino populations), we report generalization results based on the lead generalized
197 SNP (the SNP with lowest r -value in the region of the previously reported variant in GIANT). In sex
198 combined analyses, there were a total of 12 association regions across the genome that generalized to
199 HCHS/SOL for WHRadjBMI ($r < 0.05$), including three for both women-only and sexes combined, three for

200 women-only, and six for the sexes-combined analysis (**Supplementary Table 9**). A total of 15 association
201 regions generalized to HCHS/SOL for WCadjBMI, including seven sex-specific loci (two for men, five for
202 women, **Supplementary Table 10**), one for the sexes-combined only, and seven for more than one
203 stratum. Of note, we identified rs6809759 near *PROK2*, which was significantly associated with
204 WCadjBMI in HCHS/SOL for men-only and sexes-combined and was within 500 kb (+/-) of rs12330322,
205 identified in Shungin et al (35). However, this previously-identified locus did not generalize to HCHS/SOL
206 ($r>0.05$); and may represent an independent association signal in a known region (i.e. all GIANT variants
207 at this locus with $P<1\times 10^{-6}$ exhibit $r>0.05$ in HCHS/SOL and rs6809759 had a $P>1\times 10^{-6}$ in Shungin et al.
208 (35) [$P=1.4\times 10^{-1}$]). A total of 40 regions generalized to HCHS/SOL for HIPadjBMI, including 29 for sexes-
209 combined, three of which were significant for both women-only and sexes combined analyses
210 (**Supplementary Table 11**).

211 Because some of the SNPs previously reported by GIANT may not have generalized due to lack
212 of power in HCHS/SOL, we calculated individual-level genetic scores based on trait-increasing alleles for
213 each central adiposity phenotype (**Supplementary Table 12**) and sex stratum (three association tests per
214 phenotype). For genetic scores based on SNPs with $p\text{-value}<1\times 10^{-7}$ in GIANT, all association tests were
215 significant ($p\text{-value}<0.05$). For genetic scores calculated from GIANT SNPs with $1\times 10^{-7}<P<1\times 10^{-6}$, six of
216 the nine association tests were significant. Given that only three out of 27 analyses had a $p\text{-value}>0.05$,
217 there is considerable overlap in the association results of Hispanics/Latinos to those previously reported
218 in the GIANT multiethnic analysis.

219

220 **Biological Curation**

221 We examined the four SNPs (i.e. rs13301996, rs79478137, rs28692724, and rs3168072) in novel
222 loci identified in the replication analyses (**Table 1**) for association with other phenotypes, gene
223 expression, and metabolites in publicly available data using Phenoscanner (37, 38), and assessed the

224 potential regulatory role of these variants and those in LD using publicly available databases, including
225 RegulomeDB (39), Haploreg (40), UCSC GenomeBrowser (41), and GTex (42). Known associations with
226 these variants meeting Bonferroni-corrected significance after correcting for number of reported
227 associations in Phenoscanner for the four variants within each category ($P < 0.05/7631 = 6.55 \times 10^{-5}$ for
228 GWAS; $P < 0.05/88 = 5.68 \times 10^{-4}$ for gene expression; $P < 0.05/488 = P < 1.02 \times 10^{-4}$ for metabolites) are provided
229 in **Supplementary Tables 13-15**.

230 WHRadjBMI-associated variant, rs13301996, which is intronic to *CDK5RAP2* (CDK5 [cyclin-
231 dependent kinase 5] Regulatory Subunit Associated Protein 2), was significantly associated with
232 expression of 15 genes and one lncRNA across 17 tissue types (**Supplementary Table 14**). The most
233 significant of these associations was with *MEGF9* (Multiple Epidermal Growth Factor-Like Domains 9) in
234 whole blood ($P = 1.8 \times 10^{-149}$), a gene that rests 30 Kb upstream of rs1330996. This SNP is also significantly
235 associated with expression of *MEGF9* in subcutaneous adipose tissue, sun-exposed skin, and T-cells.
236 Additionally, our lead variant in *CDK5RAP2* is associated with expression of *MEGF9* in whole blood and
237 the testis; and with expression of *PSMD5* (proteasome [prosome, macropain] 26S subunit, non-ATPase,
238 5) and/or *PSMD5-AS1* in several relevant tissues, including whole blood, tibial artery, tibial nerve, lung,
239 thyroid, esophagus muscle, skeletal muscle, liver, cerebellum, and subcutaneous adipose tissues, among
240 others. Although rs13301996 is associated with gene expression for several genes, there is additional
241 support for a regulatory role of this SNP and those with which it is in high LD ($r^2 > 0.8$). For example, our
242 lead SNP lies just outside of a DNase hypersensitivity cluster, lies within a region with evidence of histone
243 modification in nine tissues including brain, skin, muscle, and heart; and likely falls in a transcription
244 factor binding site active in skeletal and lung tissue; etc. (**Supplementary Table 16**) (39-41). While there
245 are multiple lines of evidence for a regulatory role of this variant and multiple genes, rs13301996 has
246 RegulomeDB Score of 6, indicating little evidence of binding.

247 WHRadjBMI-associated SNP, rs79478137, is a low frequency variant (MAF=1.6%) intronic in
248 *SLC22A18AS* (Solute Carrier Family 22 (Organic Cation Transporter), Member 18 Antisense). This region
249 is subject to genomic imprinting (43) which has been linked with Beckwith-Wiedemann syndrome, a
250 disease caused by increased rate of growth in children (44-46). Our lead variant is associated with two
251 Electronic Health Record (EHR)-derived phenotypes (cause of death: multisystem degeneration; and
252 cause of death: tongue, unspecified) (**Supplementary Table 13**) in Phenoscanner. There is limited
253 evidence of a regulatory role for our lead SNP (RegulomeDB Score = 4), but rs79478137 is in perfect LD
254 with several variants with evidence of regulation (histone modification, open chromatin, DNase
255 hypersensitivity, transcription factor binding) in more than 50 tissues, including blood, pancreas, liver,
256 and skeletal muscle, and hippocampal tissues, etc. (**Supplementary Table 16**) (39-41).

257 Our lead SNP associated with HIPadjBMI in women, rs28692724 (NC_000014.9:g.77027445C>T),
258 is a synonymous variant exonic to *IRF2BPL* (interferon regulatory factor 2 binding protein like) that is
259 significantly associated with expression of the same gene in whole blood (**Supplementary Table 14**).
260 Additionally, this variant lies in a known CTCF binding site (RegulomDB Score = 2b), among other
261 transcription factors, and a DNase Hypersensitivity cluster (**Supplementary Table 16**) (39-41).

262 WCadjBMI-associated SNP, rs3168072, was significantly associated with existing GWAS traits
263 present in Phenoscanner, including “cause of death: other specified respiratory disorders”
264 (**Supplementary Table 13**). Additionally, rs3168072 is significantly associated with expression of several
265 genes in whole blood, but most significantly associated with expression of *TMEM258* (Transmembrane
266 Protein 258) (**Supplementary Table 14**). Rs3168072 is ~95 Kb upstream of *TMEM258*. Our lead variant is
267 likely to play a role in gene expression regulation (RegulomeDB score= 2b, “likely to affect binding”) (39).
268 Additionally, our lead variant and those in high LD ($R^2>0.8$) lie within known DNase hypersensitivity
269 regions and within active areas of histone modification, open chromatin, and likely gene enhancer
270 regions (**Supplementary Table 16**) (39-41). Our lead SNP associated with WCadjBMI, rs3168072, is

271 significantly associated with five lipid-related metabolites (**Supplementary Table 15**), including “Other
272 polyunsaturated fatty acids than 18:2,” “CH2 groups in fatty acids,” “Ratio of bis allylic bonds to double
273 bonds in lipids,” “CH2 groups to double bonds ratio,” and “Ratio of bis allylic bonds to total fatty acids in
274 lipids.”

275

276 **Discussion**

277 We performed the first large-scale GWAS of 3 central adiposity traits (i.e., WHRadjBMI,
278 WCadjBMI, and HIPadjBMI) in a sample of approximately 12,672 Hispanic/Latino individuals. We
279 identified 16 variants that were suggestively associated ($P < 1 \times 10^{-6}$) with WHRadjBMI, 22 for WCadjBMI,
280 and 28 for HIPadjBMI. Of these 66 variants that were suggestively associated with the three central
281 adiposity traits, four novel loci replicated after meta-analysis with replication samples. Additionally, we
282 demonstrated that eight previously identified GWAS loci generalized to Hispanic/Latino study
283 participants for WHRadjBMI, 10 for WCadjBMI, and 12 for HIPadjBMI in HCHS/SOL.

284

285 **Discovery of Four Novel Loci**

286 Given the large number of published GWAS on central adiposity measures, it may seem
287 surprising that four novel loci (rs13301996, rs79478137, rs28692724, and rs3168072) were mapped. We
288 ascribe this to (1) previous GWAS were primarily conducted in European populations. Indeed, all four
289 novel SNPs were absent from previous GIANT HapMap imputed analyses (35), and one (rs28692724) of
290 the four absent from a more recent GWAS that included Europeans from the UK Biobank (33); (2) the
291 consideration of a broad spectrum of ancestrally diverse Hispanic/Latino populations, including not just
292 those of Mexican ancestry, but also those with ancestry from the Caribbean, Central, and/or South
293 America (47); (3) the use of the entire 1,000 Genomes Phase I Reference panel, including populations
294 with Native American ancestry: MXL (Mexico), CLM (Colombia), and PUR (Puerto Rico); (4)

295 demonstrated differences in the patterning of body composition by ancestry (48, 49). More specifically,
296 African ancestry populations have lower body fat percentages than men and women of non-Hispanic
297 European, Native American, and East Asian ancestry at the same BMI. Additionally, non-Hispanic African
298 ancestry men and women have greater skeletal and muscle mass than their non-Hispanic European
299 ancestry counterparts, who in turn have greater skeletal and muscle mass than men and women of East
300 Asian origin (48, 50-52)

301 Recent GWAS for coding variation of waist circumference traits identified the importance of
302 central adiposity genes in lipid regulation, storage, and homeostasis (53). Similarly, we found a novel
303 association of a variant in *FADS2* (rs3168072) with WC_{adjBMI} following meta-analysis of HCHS/SOL
304 results with results from an independent sample of European descent individuals, which further implies
305 a role of this locus in central adiposity and lipid homeostasis. Genetic variations in the *FADS2* gene has
306 been associated with several traits related to obesity and cardiometabolic health, including fatty acid
307 metabolism and adipose tissue inflammation, leading to an interaction between weight loss and *FADS2*
308 genes in the regulation of adipose tissue inflammation (54). A nearby variant, rs174546 ($R^2=0.3523$,
309 $D'=0.916$ in AMR), in *FADS1* has previously been associated with four lipid traits (55). The A allele
310 (MAF=38%) is associated with greater waist circumference in our samples, and is nearly fixed among
311 sub-Saharan African populations (99% in 1000 Genomes AFR), at very high frequency in European
312 populations (97% in EUR), and at a lower frequency in East Asian (75% in EAS) and Native American
313 populations (63% in AMR). Rs3168072 is intronic to *FADS2* - a member of the fatty acid desaturase
314 (FADS) gene family and is involved in the endogenous conversion of short-chain polyunsaturated fatty
315 acids to long chain fatty acids. The *FADS* cluster of genes appears to have been under strong selection in
316 several human populations, which likely explains the large differences in allele frequencies across global
317 populations (56-59), and why previous GWAS of waist traits primarily focused on European descent
318 populations did not detect an association signal in this region.

319 We identified a novel association for WHRadjBMI with rs13301996 following meta-analysis with
320 an independent sample of African descent individuals. Rs13301996 is intronic to *CDK5RAP2*, which
321 encodes a regulator of CDK5 (cyclin-dependent kinase 5) activity (60), interacts with CDK5R1 and
322 pericentrin (PCNT) (60), plays a role in centriole engagement and microtubule nucleation (61), and has
323 been linked to primary microcephaly and Alzheimer's disease (62, 63). In addition, we identified a novel
324 association for WHRadjBMI with rs79478137 (p-value= $3.64E^{-9}$) in Hispanic/Latino women. Rs79478137
325 is intronic to the antisense *SLC22A18AS* gene, which is highly expressed in the liver and kidney, as well as
326 the gastrointestinal tract and placenta. Very little is known of the biological role of this gene (64), and
327 *SLC22A18AS* has no counterpart in mice or other rodents (65). Thus, although its genomic organization is
328 known, the regulation and function of this gene is not understood (66).

329 Lastly, we identified a novel association for HIPadjBMI at rs28692724 following meta-analysis
330 with an independent sample of European women. Rs28692724 is a synonymous variant in *IRF2BPL*,
331 which encodes a transcription factor that, acting within the neuroendocrine system, plays a role in
332 regulating female reproductive function (67).

333

334 **Differences in Association by Background Group**

335 Many of the loci mapped in this study displayed effect heterogeneity by background group. For
336 example, the *NTM* locus associated with WHRadjBMI in women, displayed nearly threefold the effect
337 size in the mainland background group compared to the Caribbean background group. Also, for the
338 women-only primary analysis, rs77186623 in the *LOC105375745* locus displayed a fourfold greater
339 effect in the Caribbean background group compared to the mainland group. These and other loci
340 displaying heterogeneity by background group (i.e. *MARCKSL1*, *C19orf67*, *RIT2*, *MAP4K4*, *COBL*, *NREP*,
341 and *ANO10*) were not validated in replication analyses, possibly due in part to heterogeneity by
342 background group.

343

344 **Limitations**

345 A limitation of this study was the small sample size within each HCHS/SOL background group.
346 However, the use of genetic-analysis groups in our analyses accounted for heterogeneity of genetic
347 effects among ethnic groups often ignored in GWAS studies. Compared to self-identified background
348 groups, genetic-analysis groups are more genetically homogeneous and lack principal component
349 outliers in stratified analysis, which may hinder detection of and adjustment for important population
350 structure when ignored (68). In addition, genetic-analysis groups allow all individuals to be classified in a
351 specific group, whereas many individuals in HCHS/SOL have a missing or non-specific self-identified
352 background (68). Therefore, by using genetic-analysis groups in our analysis rather than self-identified
353 background groups, we have increased our study's power to detect novel and previously documented
354 associations with central adiposity traits (68). Due to the diverse background of our discovery
355 population, another limitation was the lack of an ideal replication study. We attempted to overcome this
356 limitation by focusing on both multiethnic meta-analyses, which would validate those associations that
357 generalize across ancestries, and meta-analyses stratified by ancestry, which may allow for validation of
358 more population-specific associations. However, it is possible that the limited Native American ancestry
359 present across our replication cohorts may have hindered replication, and further analyses in more
360 diverse Hispanic/Latino populations are needed to confirm the relevance of promising central adiposity
361 associated loci identified in our study.

362

363 **Conclusion**

364

365 We identified 4 novel loci for central adiposity traits in a large population of Hispanic/Latino
366 Americans. We also found that several previously identified central adiposity loci discovered in

367 European American populations generalized to Hispanic / Latino Americans. Many of the loci
368 interrogated exhibit subgroup-specific effects, likely due to population history (admixture, natural
369 selection), that have resulted in changes in LD, or allele frequency differences, or due to variation in
370 etiology. These observations highlight the importance of large-scale genomic studies in ancestrally
371 diverse populations for identifying obesity-susceptibility loci that generalize and those that are ancestry-
372 specific.

373

374 **Materials and Methods**

375

376 **Study Sample**

377 Details on the study and sampling design of the Hispanic Community Health Study /Study of
378 Latinos (HCHS/SOL) have been previously described (69). Briefly, HCHS/SOL is a community based
379 prospective cohort study of 16,415 self-identified Hispanic/Latino adults aged 18-74 years at screening
380 from randomly selected households in four US field centers (Chicago, IL; Miami, FL; Bronx, NY; San
381 Diego, CA) with baseline examination (2008 to 2011) and yearly telephone follow-up assessment for at
382 least three years. The HCHS/SOL cohort includes participants who self-identified as being Central
383 American (n=1,732), Cuban (n=2,348), Dominican (n=1,473), Mexican (n=6,472), Puerto-Rican (n=2,728),
384 and South American (n=1,072). The goals of the HCHS/SOL are to describe the prevalence of risk and
385 protective factors for chronic conditions (e.g. cardiovascular disease (CVD), diabetes and pulmonary
386 disease), and to quantify all-cause mortality, fatal and non-fatal CVD and pulmonary disease, and
387 pulmonary disease exacerbation over time. The baseline clinical examination (70) included
388 comprehensive biological (e.g., anthropometrics, blood draw, oral glucose tolerance test, ankle brachial
389 pressure index, electrocardiogram), behavioral (e.g. dietary intake assessed with two 24-hour recalls,
390 physical activity assessment by accelerometer and self-report, overnight sleep exam for apneic events,

391 tobacco and alcohol assessed by self-report), and socio-demographic (e.g., socioeconomic status,
392 migration history) assessments. This study was approved by the institutional review boards at each field
393 center, where all subjects gave written informed consent.

394 Participants in HCHS/SOL self-identified their background as Mexican, Central American, South
395 American (mainland), Puerto Rican, Cuban, or Dominican (Caribbean). Some participants chose “more
396 than one,” “other,” or chose not to self-identify. We addressed the missing or inconsistent data in self-
397 identified background groups by defining “genetic analysis groups,” described in Conomos et al (68). To
398 increase power in this analysis, we chose to stratify by the broader mainland or Caribbean categories
399 rather than more specific groups. In this paper, we will use the term “background group” to refer to a
400 super-group of genetic analysis groups by geographic region, mainland or Caribbean. Hispanics/Latinos
401 have admixed ancestry from three continents: Africa, America, and Europe. In general, participants from
402 the mainland group have higher proportions of American ancestry and lower African ancestry, while
403 participants in the Caribbean group have higher proportions of African ancestry (68).

404

405 **Phenotypes**

406 All measurements were taken from the baseline visit. Participants were dressed in scrub suits or
407 light non-constricting clothing and shoes were removed for weight and height measurements. WC and
408 HIP were measured using Gulick II 150 and 250 cm anthropometric tape and rounded to the nearest
409 centimeter (cm). Height was measured using a wall mounted stadiometer and rounded to the nearest
410 cm, and weight measured with a Tanita Body Composition Analyzer, TBF-300A to the nearest tenth of a
411 kilogram (kg). Height and weight were used to calculate BMI (kg/m^2). We applied a log₁₀ transformation
412 on HIP, due to its non-normal trait distribution.

413

414 **Genotyping**

415 Our analyses included 7,472 women and 5,200 men of mainland (Mexican, Central and South
416 American) or Caribbean (Puerto Rican, Cuban, and Dominican) ancestry residing in the U.S. All
417 participants were genotyped on the Illumina SOL Omni2.5M custom content array, which was
418 subsequently used to impute millions of additional variants, based on the entire 1,000 Genomes Phase I
419 Reference panel, including populations with Native American ancestry: MXL (Mexico), CLM (Colombia),
420 and PUR (Puerto Rico). Pre-phasing was performed using SHAPEIT, followed by imputation with
421 IMPUTE2 (71, 72).

422

423 **Discovery Analyses**

424 Due to known differences in genetic effects on waist and hip traits between men and women
425 (35, 73, 74), we analyzed associations stratified by sex for each trait, in addition to the entire sample.
426 We used linear mixed-model regression, assuming an additive genetic model adjusted for age, age²,
427 study center, sample weights, genetic analysis subgroup (68, 75), principal components to account for
428 ancestry, population structure using kinship coefficients and sample eigenvectors, household, census
429 block group, and sex in the combined analysis. Kinship, household, and block group were treated as
430 random effects in each model. Sample weights were incorporated in our models as a fixed effect to
431 account for oversampling of the communities in the 45-74 age group (n=9,714, 59.2%) which was
432 intended to facilitate the examination of HCHS/SOL target outcomes. HCHS/SOL sampling weights are
433 the product of a “base weight” (reciprocal of the probability of selection) and three adjustments: 1) non-
434 response adjustments made relative to the sampling frame, 2) trimming to handle extreme values (to
435 avoid a few weights with extreme values being overly influential in the analyses), and 3) calibration of
436 weights to the 2010 U.S. Census according to age, sex, and Hispanic background. We used genetic-
437 analysis groups in our analyses accounted for heterogeneity of genetic effects among ethnic groups.
438 Compared to self-identified background groups, genetic-analysis groups are more genetically

439 homogeneous and lack principal component outliers in stratified analysis, which may hinder detection of
440 and adjustment for important population structure when ignored (68). In addition, genetic-analysis
441 groups allow all individuals to be classified in a specific group, whereas many individuals in HCHS/SOL
442 have a missing or non-specific self-identified background (68). Also, we conducted stratified analyses by
443 region (mainland vs. Caribbean) to identify potential heterogeneity in effect by background group. We
444 examined heterogeneity across background group using I^2 statistics calculated using METAL (76) and
445 tested for significant interaction ($P_{diff} < 0.05$) by background group using EasyStrata (77).

446 To decrease the number of spurious associations, we filtered all results on minor allele
447 frequency (MAF) $< 0.5\%$, Hardy-Weinberg Equilibrium (HWE) $P < 1 \times 10^{-7}$, minor allele count (MAC
448 [effective N]) < 30 (68). Additionally, we categorized suggestive loci as those with variants reaching
449 $P < 1 \times 10^{-6}$ and with at least one additional variant within 500 kb+/- with a $P < 1 \times 10^{-5}$. We used regional
450 association plots produced in LocusZoom to visualize association regions using 1000 Genomes Admixed
451 American (AMR) reference population for LD (<http://locuszoom.sph.umich.edu/>).

452

453 **Local Ancestry Estimation**

454 We estimated local ancestry (African, Native American, and European) using RFMix (78), which
455 applies a conditional-random-field-based approach for estimation, to inform differences by background
456 group. We used 236,456 genotyped SNPs available in both HCHS/SOL and reference-panel datasets in
457 the Human Genome Diversity Project (HGDP) (79), HapMap 3 (80), and 1000 Genomes phase 1 for
458 detecting African, Native American, and European ancestry. We used BEAGLE (v.4) to phase and impute
459 sporadic missing genotypes in the HCHS/SOL and reference-panel datasets (81).

460

461 **Replication and Meta-Analyses**

462 An aim of our study was to identify genetic variants that contribute to central adiposity which
463 may vary by ancestry; therefore, we sought to replicate our association findings using 1000 Genomes
464 imputed GWAS data available in independent cohorts including eight studies with Hispanics/Latinos (HL:
465 N up to 12,341), three studies with African-Americans (AA; N up to 12,496), and one study with
466 European-Americans (EUR: N up to 8,845). Study design and descriptive statistics for each replication
467 study are provided in **Supplementary Table 1**. Each replication study excluded individuals that were
468 pregnant or exhibited extreme values for waist or hip measures (outside of ± 4 SD from the mean). Each
469 study used measures from a single visit with the greatest sample size. We used linear regression (or
470 linear mixed effects models if the study had related individuals) association analyses on the trait
471 residuals after adjustment for age, age², principal components to account for ancestry, BMI, other study
472 specific factors (e.g. study center), and sex in the sex combined analysis, stratified by race/ethnicity
473 where applicable for each SNP that reached suggestive significance ($P < 1 \times 10^{-6}$) in the discovery analysis.

474 We employed a fixed-effects meta-analysis using the inverse variance-weighted method for
475 WHRadjBMI and WCadjBMI. For HIPadjBMI, due to trait transformations, we used sample size weighted
476 meta-analysis. All meta-analyses were implemented in METAL (82). We conducted meta-analyses
477 stratified by race/ethnicity group and combined across groups. We included SNPs with a study and
478 stratum specific imputation quality (Rsq) greater than 0.4, Hardy-Weinberg Equilibrium P-value greater
479 than 1×10^{-7} , and a minor allele count (MAC) greater than five. To declare statistical significance for
480 replicated loci, we required in each replication sample a trait and stratum-specific $P < 0.05$ with a
481 consistent direction of effect with discovery, and genome-wide significance ($P < 5 \times 10^{-8}$) when meta-
482 analyzed together with HCHS/SOL.

483

484 **Generalization**

485 To examine whether previously reported association regions generalized to the HCHS/SOL, we
486 downloaded the publicly available multi-ethnic (European, Asian, and African ancestry) GWAS results
487 from the Genetic Investigation of Anthropometric Traits (GIANT) consortium (14) for HIPadjBMI,
488 WHRadjBMI, and WCadjBMI
489 (https://portals.broadinstitute.org/collaboration/giant/index.php/GIANT_consortium_data_files#GIANT
490 [_consortium_2012-2015_GWAS_Metadata_is_Available_Here_for_Download](https://portals.broadinstitute.org/collaboration/giant/index.php/GIANT_consortium_data_files#GIANT)), in men, women, and
491 sexes combined, and applied the framework of Sofer et al. (2016) for generalization testing (83). We
492 took all variant associations with $P < 1 \times 10^{-6}$ in GIANT and identified the matching association test in
493 HCHS/SOL. For each such association, we calculated a directional FDR r -value, by combining the P -values
494 from GIANT and HCHS/SOL, while accounting for multiple testing and for the direction of estimated
495 associations in each of the studies. Then, an association was declared as generalized, while controlling
496 for the False Discovery Rate (FDR) at the 0.05 level, if its r -value was smaller than 0.05. Note that
497 multiple SNPs from the same region were tested. Therefore, in an iterative procedure, we pruned the
498 results list by identifying the SNP with the lowest r -value in an analysis, then finding all SNPs in a 1MB
499 region around it and removing them from the list. Thus, the number of generalized regions is the
500 number of generalized SNPs in the pruned list.

501 We also hypothesized that some regions did not generalize due to lack of power (the HCHS/SOL
502 sample size is much smaller than the GIANT sample size). To test this, we took all tested SNPs from the
503 non-generalized regions and considered the GIANT multi-ethnic GWAS results. In an iterative procedure,
504 we pruned the list by first identifying the SNP with lowest GIANT P -value in the analysis, then found all
505 SNPs in a 1MB region around it and removed them from the list. We repeated until no SNPs remained.
506 All the SNPs in the pruned list were selected solely based on their GIANT P -values. Since there were
507 many such variants, we further grouped them according to their P -values. Groups were formed by trait,
508 sex (men, women, combined), and GIANT P -value (between 10^{-6} to 10^{-7} , between 10^{-7} to 10^{-8} , and

509 smaller than 10^{-8}). For each such group of SNPs, we created a genetic risk score (GRS) in HCHS/SOL. For
510 each sex stratum and each group of SNPs, the value of the GRS was the sum of all trait increasing alleles
511 in that group. We tested the GRS in the appropriate analysis group (men, women, combined). A low *P*-
512 value implies that some of the SNPs in the group are likely associated with the trait in HCHS/SOL.

513

514 **Biological Curation**

515 To gain further insight into the possible functional role of the identified variants and to assess
516 the relevance of our identified variants with other phenotypes, we conducted lookups of our replicated
517 variants in multiple publicly available databases, including PhenoScanner (37), RegulomeDB (39),
518 Haploreg (40), and UCSC GenomeBrowser (41). Additionally, we conducted lookups of nearby genes in
519 GTex (42). The R package HaploR was used to query HaploReg and RegulomeDB ([https://cran.r-](https://cran.r-project.org/web/packages/haploR/vignettes/haplor-vignette.html)
520 [project.org/web/packages/haploR/vignettes/haplor-vignette.html](https://cran.r-project.org/web/packages/haploR/vignettes/haplor-vignette.html)).

578 authors thank the WHI investigators and staff for their dedication, and the study participants for making
579 the program possible. A full listing of WHI investigators can be found at:
580 http://www.whiscience.org/publications/WHI_investigators_shortlist.pdf.

581

582 **Data Availability Statement**

583 Raw genetic data used in the discovery analysis for this project is available through request on dbGAP
584 (dbGaP Study Accession: phs000810.v1.p1). Additionally, the full GWAS summary results for common
585 variants with a MAF>1% will be made available upon request to the author and on the NHGRI-GWAS
586 Catalog (upon publication).

587

588 **Conflict of Interest Statement**

589 The authors have no conflicts of interest to disclose.

838 **Figures**

839 **Figure 1.** WCadjBMI Synthesis View plot that shows $-\log_{10} P$ -values, beta (effect estimate), effect/coded
 840 allele frequency (CAF), and sample size across analysis samples for all loci that reached suggestive
 841 significance in one or more of our discovery strata. This chart also shows the coded allele frequency
 842 (CAF) of each of our top loci by background group and by 1000 genomes reference panel (European -
 843 EUR, Latin American - AMR, and African - YRI).

844

845

846

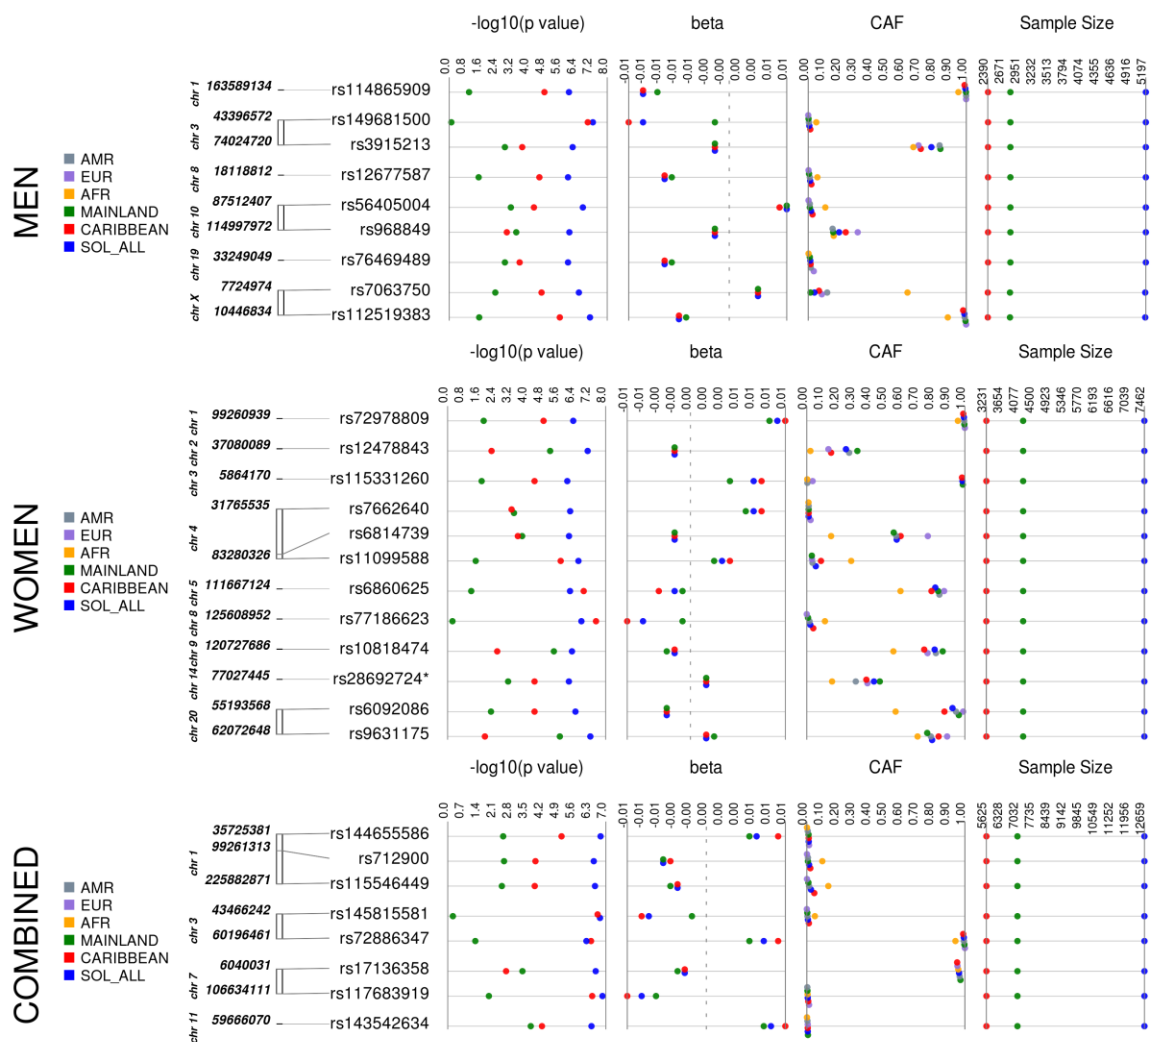

847 **Figure 2.** WHRadjBMI Synthesis View plot that shows $-\log_{10} P$ -values, beta (effect estimate),
 848 effect/coded allele frequency (CAF), and sample size across analysis samples for all loci that reached
 849 suggestive significance in one or more of our discovery strata. This chart also shows the coded allele
 850 frequency (CAF) of each of our top loci by background group and by 1000 genomes reference panel
 851 (European - EUR, Latin American - AMR, and African - YRI).

852

853

854 **Figure 3.** HIPadjBMI Synthesis View plot that shows the $-\log_{10} P$ -values, beta (effect estimate),
 855 effect/coded allele frequency (CAF), and sample size across analysis samples for all loci that reached
 856 suggestive significance in one or more of our discovery strata. This chart also shows the coded allele
 857 frequency (CAF) of each of our top loci by background group and by 1000 genomes reference panel
 858 (European - EUR, Latin American - AMR, and African - YRI).
