Title:

Prediction of severe COVID-19 cases requiring a ventilator in Tokyo, Japan

Keywords: COVID-19, medical exhaustion, prediction, severe case, ventilator

Summary

Background: To avoid exhaustion of medical resources by COVID-19, policy-makers must predict care needs, specifically the proportion of severe cases likely to need ventilator care.

Objective: This study was designed to use a statistical model to elucidate dynamics of severe cases in Tokyo and to discuss the timing of effective policy activation. Methods: The study extended from April 27 through October 18, 2020 in Japan's Tokyo Metropolitan area. Medical exhaustion was defined as use of more than half of the ventilator capacity available before the COVID-19 outbreak. We regressed the number of severe cases on the newly onset patients of more than 14 days prior. As earlier research indicated, the COVID-19 severity changed at the end of May. Therefore, we added dummy variables to reflect changing severity from June and its product with newly onset patients as the explanatory variable. Then we calculated the threshold using R(t): R(t)=0.99 for the number of patients 14 days prior was used as a threshold at which strong countermeasures should be activated to keep to avoid medical exhaustion. Results: The critical number signaling medical exhaustion in Tokyo was defined as 655 cases. We selected 15, 30, 60 and 90 days prior as explanatory variables for explaining the number of severe cases. A coefficient of determination larger than 0.95 was inferred

as indicating good fit. The threshold was estimated as more than 4500 cases for

R(t)=1.1 and monotonically decreasing by R(t) to be 600 cases for R(t)=2.5.

Discussion and Conclusion: Results showed that newly onset patients reported more

than 14 days prior can explain the number of severe cases very well. We also confirmed

the threshold number of patients 14 days prior by R(t) for which strong countermeasures

should be activated to avoid medical exhaustion with R(t)=0.99. This method is

expected to be useful for countermeasure activation policies for Tokyo.

1 Introduction

2	As of October 28, 2020, the World Health Organization reported more than 42
3	million confirmed COVID-19 cases and about 1.15 million deaths worldwide (1). In
4	Japan, the outbreak reached its peak at the end of July. By October 29, 2020,
5	approximately 100 thousand cases and 1.7 thousand deaths had been reported (1).
6	For the 29,601 cases reported from February 1 through August 5, 2020, the
7	case-fatality rate (CFR) was low for people 59 years old and younger. Nevertheless,
8	among patients 60 years old and older, CFR was found to increase with age. Similarly,
9	probabilities of ICU admission and ventilator use increased rapidly with age (2).
10	Patients with underlying diseases such as hypertension or diabetes constituted high-risk
11	groups for severe cases of COVID-19 (3,4).
12	The Japanese government set guidelines for countermeasures against COVID-19 on
13	August 28, emphasizing caution for elderly people and high-risk individuals with
14	underlying diseases (5). Based on those guidelines, medical resource allocations
15	thereafter emphasized high-risk groups, including elderly people, rather than patients
16	with mild symptoms or asymptomatic patients.
17	Given these circumstances, understanding and predicting the proportion of severe
18	cases requiring ventilator treatment are necessary for policy makers if a strong policy

19	requiring self-restriction of travel is to be made, or if customer-service businesses must
20	be closed. Therefore, this study was conducted to elucidate the dynamics of severe cases
21	in Tokyo, with discussion of the timing of activating countermeasure policies.
22	Although we applied mathematical models to outbreaks of COVID-19 in Japan,
23	such models are unable to explain why the outbreak reached a peak at the end of July
24	under conditions of no herd immunity or lock-down. Actually, at that time in late July,
25	the Japanese government had encouraged domestic travel and thereby promoted the
26	spread of the outbreak. Nevertheless, the outbreak was contained in August. Therefore,
27	to date, no mathematical model has been able to explain the outbreak in Japan. Instead,
28	we examined a statistical model rather than a mathematical model to explain the course
29	of the outbreak. We propose some thresholds that are useful to signal activation of
30	strong countermeasures.
31	
32	Methods
33	Severe cases of COVID-19 were defined as requiring hospitalization of patients
34	with required use of a ventilator. The study period extended from April 27, when severe
35	cases under the current definition began to be reported in Tokyo, to October 18, 2020.
36	The Tokyo Metropolitan area of Japan was the study area. Medical exhaustion was

37	defined as patients using more than half of the ventilator capacity available before the
38	COVID-19 outbreak.
39	We regressed the number of severe cases on the newly onset patients reported more
40	than 14 days prior. As earlier studies have indicated, the severity of COVID-19 changed
41	at the end of May. Therefore, we added dummy variables to reflect changing severity
42	from June and its product with newly onset patients as an explanatory variable. We
43	selected a formula maximizing the adjusted coefficient of determination.
44	Then, we calculated the threshold by assuming constant $R(t)$ after October 19, 2020.
45	The timing of $R(t)=0.99$ was assessed for activation of strong countermeasures to avoid
46	medical facility exhaustion, with activation occurring when the number of patients 14
47	days prior reached this criterion level. Medical facility exhaustion was defined as
48	patients requiring ventilator use exceeding half of the ventilator capacity available
49	before the COVID-19 outbreak.
50	The study period for the epidemic curve of symptomatic patients was January 16,
51	2020 through October 18, 2020. For severe cases, it was April 27, 2020, when severe
52	cases were defined as patients who needed ventilators, through October 18, 2020.
53	Because incubation periods and delays of reporting varied after onset of symptoms, data
54	of the prior month were expected to be underreported. Therefore, we did not use the

55	final month of data available to us. However, collection of data of patients using a
56	ventilator started April 27 in Tokyo. Therefore, data of ventilator usage on or before
57	April 26 were not used for this study. The study area was metropolitan Tokyo, with 14
58	million residents. The epidemic curve and information about severe cases in Tokyo
59	were provided by the Tokyo Metropolitan Government (6).
60	We also performed out of sample prediction assuming that $R(t)$ will be constant
61	from October 19, 2020. We calculated the threshold to activate strong policy measures
62	for reducing $R(t)$ to be 0.99 for the number of newly onset patients in a day in terms of
63	R(t). Such measures might include some requirements of voluntary restrictions against
64	going out of the home or shutting down customer-service businesses. Under such
65	policies, one can expect to avoid exhaustion of medical resources and keep the need for
66	ventilators lower than 655.
67	Finally, to evaluate the model's predictive power, we performed out of sample
68	forecasting prospectively for 21 days from December 3, 2020. The parameters for
69	forecasting were fixed. The estimation result used data obtained through October 18,
70	2020.
71	

72 Ethical considerations

73	All information used for this study was collected under the Law of Infection
74	Control, Japan. Published data were used. Therefore no ethical issue is posed by the
75	procedures used to conduct this study.
76	
77	Results
78	In Tokyo, we observed 3,072 patient days of ventilator use from April 27, 2020
79	through the end of July. From January 16, 2020 through the end of July, 11,619 patients
80	with symptoms were reported.
81	Because Tokyo had 2,456 ventilators before the COVID-19 outbreak and because
82	1,310 ventilators were unused by patients (7), if patients needing ventilators were to
83	become more numerous than 655, the situation would be designated as medical facility
84	exhaustion.
85	Figure 1 depicts severe cases and newly onset patients. Severe cases fluctuate with
86	a longer lag than the onset patients. The estimation results are presented in Table 1.
87	Because 120 days before April 27 was earlier than January 16, when the initial case in
88	Tokyo showed onset, the specification with onset patients 120 days prior includes fewer
89	observations than other specifications. Based on adjusted coefficients of determination,
90	we selected the model with up to 90 days prior. Its adjusted coefficient of determination

91 was higher than 0.95. Figure 2 depicts the observed and fitted numbers of severe cases.

92	It is apparent	that these	were almost	equal to	o one another
----	----------------	------------	-------------	----------	---------------

- 93 The estimated thresholds of the number of patients 14 days prior by R(t) in which
- 94 the timing of activation of strong countermeasures to be R(t)=0.99 should be activated
- 95 to avoid medical exhaustion are shown at Figure 3. The threshold was estimated as
- 96 more than 4500 for R(t)=1.1, decreasing monotonically by R(t) to be 600 for R(t)=2.5.
- 97 Figure 4 depicts out of sample forecasting prospectively for 21 days from
- December 3, 2020 through February 23, 2021. The observed peak was January 20, 2021,
- but the peak in forecasting was January 29, 2021. Before the peak date, forecasting was
- significantly lower than the observed figure, except for early December. However, after
- 101 the peak date, no significant difference was found among them.

102

103 Discussion

Many mathematical models have been applied to the outbreak of COVID-19 worldwide (8,9). Unfortunately, these have not succeeded in explaining the course of COVID-19 outbreaks.

Especially, in Japan, two peaks were experienced through October. The first peak
was that of earlier April; the second one was at the end of July. The first peak might

109	explain the mathematical model with restriction of going out (10) because, since
110	mid-March, the rate of going out declined, as shown in Apple data. However, the
111	second peak is inexplicable by the mathematical model. Herd immunity, of course, was
112	not achieved. No lock-down was activated in Japan at all. Probably, the "new normal"
113	lifestyle with mask-wearing, social distancing, and restrictions against numerous dining
114	or night-life establishments became common.
115	Actually, at that time, the government encouraged domestic travel. It promoted the
116	spread of the outbreak. However, the outbreak was contained in August. Therefore, to
117	date, no mathematical model has been sufficient to explain the outbreak in Japan. The
118	policy for severe cases cannot be discussed using mathematical models.
119	Instead, we used a statistical model. It might always show some association of
120	variables for which there is no causality. We showed clear association among severe
121	cases and patients who had experienced onset 15 days prior. Moreover, we showed the
122	threshold of the number of patients 14 days prior by $R(t)$, for which the timing of
123	activation of strong countermeasures to be $R(t)=0.99$ should be activated to avoid
124	medical exhaustion. Therefore, the statistical model was probably more useful than the
125	mathematical model for countermeasures against COVID-19.

126 Regarding the increase phase in June and July, the number of newly onset patients

127	increased from about 10 to 350 during 60 days. If one assumes an average incubation
128	period to be about 6 (10), then the average $R(t)$ during this period was
129	$1.43 = (350/10)^{(6/60)}$. Figure 3 depicts the threshold as around 2200 at R(t)=1.43. The

peak at the end of July was 350. Therefore, the peak at the end of July accounted for

131 only 16% of the threshold.

130

We used no information before t-14. Reporting was usually delayed from onset up 132to 31 days (10). Therefore, the number of newly onset patients at the same day was that 133which was usually developing dynamically for at least two weeks. Information of the 134final two weeks prior to the estimate is not reliable. Therefore, we ignored information 135during the final two weeks of the study period. Moreover, because the epidemic curve 136137changes gradually, information related to day t is closely correlated with information 138related to day t-1. Therefore, we used no information related to consecutive days. We used the number of newly onset patients with 15-30 day intervals as explanatory 139140variables.

Prospective out of sample forecasting in Figure 4 shows good fit. Especially in the declining phase, it fits very well. Therefore, results demonstrated that the estimated model can predict outcomes well for 21 days.

144 Some limitations might have affected this study. First, we used dummy variables

145	after June to reflect the disease's decreasing severity. However, we do not understand
146	the reason why. It might be attributable to mutations of the COVID-19 virus.
147	Alternatively, treatment for patients might have improved since June. Or younger and
148	therefore milder patients accounted for a larger proportion of the patients than before
149	June. Moreover, the severity of the disease would decrease if a new drug were
150	developed. It might alternatively increase if some mutation were to strengthen its
151	pathogenicity. Severity should be monitored to improve the fit of the statistical model.
152	Secondly, definitions of severe cases differed among prefectures, even in Japan.
153	Moreover, they probably varied among countries. It remains unknown whether the
154	approach used for the present study is applicable to other prefectures than Tokyo or
155	other countries with other definitions of severity. We should check the robustness of
156	usefulness of the statistical model in other areas in Japan or other countries.
157	Thirdly, we might specifically examine only elderly patients or patients older than
158	50 as explanatory variables. If the reason for lower severity after June was the larger
159	proportion of younger patients, then it might be controlled by specifically examining
160	elderly patients as a high risk group. Exploration of that point remains as a challenge for
161	future research efforts.
162	

163 Conclusion

164	Results demonstrated that newly onset patients more than 14 days prior can
165	explain the number of severe cases very well. The prospective out of sample forecasting
166	used for this study can predict observations well for 21 days. Results also show a
167	threshold of the number of patients 14 days prior by $R(t)$. Timing of the activation of
168	strong countermeasures should be $R(t)=0.99$ to avoid medical facility exhaustion. That
169	signal might be useful for countermeasure activation in Tokyo. Careful real-time
170	monitoring of $R(t)$ and newly onset patients are expected to be extremely important for
171	timing of the activation of strong policy measures.
